THE DISEASES OF WOMEN.

Including their Pathology, Causation, Symptoms, Diagnosis, and Treatment.

BY ARTHUR W. EDIS, M.D., LOND., F.R.C.P.; M.R.C.S.

ASSISTANT OBSTETRIC PHYSICIAN TO THE MIDDLESEX HOSPITAL, LONDON. LATE PHYSICIAN TO THE BRITISH LYING-IN HOSPITAL.

In one handsome octavo volume of 576 pages, with 149 illustrations. Cloth, $3; leather, $4. (Just Ready.)

Dr. Edis may be congratulated on having produced a most readable and trustworthy guide to the diseases of women. It is profusely illustrated and contains drawings of all the essential gynæcological instruments. The index is copious, and will facilitate reference. Dr. Edis has followed the course which might with advantage be more generally followed, of giving the names of his authorities not only in the case of illustrations, but in quotations from other authors. The work is up to date, and is evidently that of one who has specially studied the diseases of women. It is sure to be popular with students as well as practitioners.—*British Med. Journ.*, Oct. 15, 1881.

It is some time since so succinct and withal complete an account of the Diseases of Women has appeared, as Dr. Edis's manual. Its order and clearness are remarkable. The book will be welcome as well on account of its intrinsic merits, as because it will fill a place in gynæcological literature which was empty.—*London Med. Rec.*, Oct. 15, 1881.

A MANUAL OF ORGANIC MATERIA MEDICA.

Being a Guide to Materia Medica of the Vegetable and Animal Kingdoms.

FOR THE USE OF STUDENTS, DRUGGISTS, PHARMACISTS, AND PHYSICIANS.

BY JOHN M. MAISCH, PHAR. D.,

PROFESSOR OF MATERIA MEDICA AND BOTANY IN THE PHILADELPHIA COLLEGE OF PHARMACY.

In one very handsome 12mo volume of 460 pages, with 194 beautiful illustrations on wood. Cloth, $2.75. (Just Ready.)

DALTON'S PHYSIOLOGY. New Edition. Just Ready.

A TREATISE ON HUMAN PHYSIOLOGY. Designed for the Use of Students and Practitioners of Medicine. By JOHN C. DALTON, M.D., Professor of Physiology in the College of Physicians and Surgeons in New York, etc. Seventh Edition, thoroughly revised and rewritten. With numerous illustrations on wood. In one very beautiful octavo volume of 750 pages.

The reputation which this work has acquired, as a compact and convenient summary of the most advanced condition of human physiology, renders it only necessary to state that the author has assiduously labored to render the present edition worthy a continuance of the marked favor accorded to previous issues, and that every care has been bestowed upon the typographical execution of it, to make it, as heretofore, one of the handsomest productions of the American press.

NERVOUS DISEASES, THEIR DESCRIPTION AND TREATMENT.

BY ALLAN McLANE HAMILTON, M.D.

ATTENDING PHYSICIAN TO THE HOSPITAL FOR EPILEPTICS AND PARALYTICS, BLACKWELL'S ISLAND, NEW YORK, AND AT THE OUT-PATIENTS DEPARTMENT OF THE NEW YORK HOSPITAL.

Second Edition, Thoroughly Revised and Much Improved. In one handsome octavo volume of 600 pages, with 72 illustrations. Cloth, $4.00. (Just Ready.)

EXTRACT FROM THE PREFACE TO THE SECOND EDITION.

In presenting a new edition of my book I wish to express to the profession my hearty appreciation of the favorable reception accorded to the first, which has been out of print for several months. I thank my impartial reviewers, and take pleasure in saying that wherever possible, I have endeavored to adopt their suggestions, and I trust, have succeeded in remedying the faults, many of which are unavoidable in a first edition.

The present edition is enlarged by nearly one hundred pages, and contains many new illustrations, in fact this feature has undergone an almost entire change. The enlargement is a matter of necessity, owing to the recent advances in our knowledge of neurological medicine. I have used certain portions of my essay, which received the prize of the American Medical Association in 1879, in the preparation of a chapter upon diseases of the lateral columns of the spinal cord. Other chapters have been remodelled and, I hope, improved, especially in regard to the introduction of matter relative to localization of disease in the brain and spinal cord.

THE ESSENTIALS OF THE PRINCIPLES AND PRACTICE OF MEDICINE.

A HANDY-BOOK FOR STUDENTS AND PRACTITIONERS.

By HENRY HARTSHORNE, M.D.

LATE PROFESSOR OF HYGIENE IN THE UNIVERSITY OF PENNSYLVANIA.

Fifth Edition, Revised and Improved. In one handsome royal 12mo volume of 670 pages, with 144 illustrations. Cloth, $2.75; half bound, $3.00. (Just Ready.)

The great success which has exhausted four large editions of this work shows that the author has succeeded in supplying a want felt by a large portion of the profession. It has also enabled him in successive revisions to perfect the details of his plan, and to render the work still more worthy of the favor with which it has been received. In the present edition several hundred brief additions have been made, a number of new subjects have been written upon, especially in connection with the Pathology of the Nervous System, the illustrations have been considerably increased, and a large number of new and carefully selected formulæ for the administration of medicines have been introduced. An account is given, also, in this edition for the first time, of the method of prescribing according to the metrical system, and a Section is added upon Eyesight, its Examination and Correction. In presenting this edition, therefore, the publishers feel that it is in every way worthy of the continuance of the favor hitherto accorded this work.

Fourteen years have elapsed since the publication of the first edition of Hartshorne's *Essentials*, and still it remains the best book of its kind ever published. To this, the fifth edition, numerous additions have been made, in the preparation of which the most recent contributions to medical literature have been consulted.—*Med. and Surg. Reporter*, Nov. 5, 1881.

It has long held a first place as a text-book with students and young physicians, and, from the improvements which appear in this last revision, we feel sure that it will, for a long time, continue to maintain its position.—*Cincinnati Med. News*, Nov., 1881.

SMITH ON CHILDREN. New Edition. Just Ready.

A COMPLETE PRACTICAL TREATISE ON THE DISEASES OF CHILDREN. By J. LEWIS SMITH, M.D., Clinical Professor of Diseases of Children in the Bellevue Hospital Medical College, New York. Fifth edition, thoroughly revised and rewritten. In one handsome octavo volume of 836 pages, with illustrations. Cloth, $4.50; leather, $5.50; very handsome half Russia, raised bands, $6.

The rapidity with which successive editions of this work have been issued, attest its very marked popularity and usefulness to the profession. In fact the profession has learned to recognize this high authority as a thoroughly safe and trustworthy guide in all questions relating to the diseases of infancy and childhood, and to appreciate the author's effort to keep the work up to the requirements of the practice of the day. Whatever is new in pathology and treatment the author has added, and in order to more fully meet the wants of professional knowledge, he has treated of a few additional diseases. A work so well and favorably known does not come within the reach of criticism.—*Md. Med. Journ.*, Nov. 15, 1881.

Dr. Smith's treatise is universally recognized as a work based on a high standard of professional knowledge, and is written in a forcible, clear, elegant style, which commends itself to the favorable consideration of the practitioner and general reader.—*Col. and Clin. Rec.*, Dec. 15, 1881.

BARTHOLOW ON ELECTRICITY. Just Ready.

A PRACTICAL TREATISE ON ELECTRICITY IN ITS APPLICATIONS TO MEDICINE. By ROBERTS BARTHOLOW, A.M., M.D., LL.D., Professor of Materia Medica and General Therapeutics in the Jefferson Medical College of Philadelphia. In one very handsome octavo volume of about 300 pages, with 96 illustrations. Cloth, $2.50.

We have not yet come across a book that can compare with this in clearness and simplicity of statement. We have for a long time needed a text-book on medical electricity, condensed and yet complete, and this want has been well supplied by the distinguished author. The illustrations are elegant, and the book as a whole is a valuable addition to the collection of any student or practitioner.—*Buffalo Med. and Surg. Journ.*, June, 1881.

MITCHELL ON DISEASES OF THE NERVOUS SYSTEM. Just Ready.

LECTURES ON DISEASES OF THE NERVOUS SYSTEM, ESPECIALLY IN WOMEN. By S. WEIR MITCHELL, M.D., Physician to the Orthopædic Hospital and Infirmary for Diseases of the Nervous System. In one very handsome 12mo volume of about 250 pages, with five lithographic plates. Extra cloth, $1.75.

Dr. Mitchell's large clinical experience with this class of diseases, and his well-known ability as an acute and critical observer, give to his statements a force and apparent value that would be wanting in a work by a less distinguished author. In conclusion, we will say of the work that it is in very many respects an excellent one, and one that we have found profit in reading.—*Journ. of Mental and Nervous Disease*, July, 1881.

This book consists of a pleasant series of lectures by a distinguished American physician. The subjects dealt with are mostly unusual or puzzling varieties of numerous diseases in women, and the mode of treating them. The book is a good and useful one, and will repay perusal.—*London Journ. of Psychological Med. and Mental Pathology*, Oct., 1881.

GROSS ON DISORDERS OF THE MALE SEXUAL ORGANS. Just Ready.

A PRACTICAL TREATISE ON IMPOTENCE, STERILITY, AND ALLIED DISORDERS OF THE MALE SEXUAL ORGANS. By SAMUEL W. GROSS, A.M., M.D., Lecturer on Genito-Urinary and Venereal Diseases in the Jefferson Medical College, Philadelphia. In one very handsome octavo volume of 174 pages, with 16 illustrations. Cloth, $1.50.

We highly commend the book to the profession, and believe and trust it will meet with a large sale. The author is a clear and concise writer, and every page of this treatise gives evidence of his thorough familiarity with recent research, and with the latest journal literature. The book is a thoroughly scientific exposition of our present knowledge of the subjects treated of; its pages are rich in information of high value to the practitioner; and once read, will be frequently referred to.—*St. Louis Courier of Med.*, Nov., 1881.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XL. SATURDAY, JANUARY 7, 1882. NO. 1.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE ANTIPYRETIC TREATMENT OF TYPHOID FEVER,

BY BATHS, SPONGING THE BODY, AND THE WET SHEET.

Delivered at Bellevue Hospital,

BY AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

GENTLEMEN: As introductory to the subject of this lecture, I ask to be indulged in giving some personal reminiscences. More than thirty years ago my interest was enlisted in the clinical study of the continued fevers. This was not long after the publication, in this country, of the translation by Bowditch of the great work of Louis, containing researches which established the clinical history of the typhoid fever in France, of that day, and not less of the typhoid fever of to-day in all countries. The observations by Gerhard, Shattuck, and others had recently been published, showing that typhus fever, as existing in Ireland, and as imported into this country, was a species of fever distinct from the typhoid fever studied by Louis. It was a mooted question at that time whether typhus and typhoid fever were varieties of one species of fever, or essentially different diseases. This question elicited much discussion at the annual meeting of the New York State Medical Society in 1850, and a committee was appointed, of which I was made chairman, to collect facts relating to the question. I was in this way led to study analytically, following the numerical method of Louis, all the cases of continued fever which, up to that time, I had recorded. The number of cases amounted to fifty-two. The results of the analytical study of those cases were embodied in a report. In 1851 I had collected the recorded histories of forty-eight additional cases of typhus and typhoid fever. I subjected these cases to an analytical study, and embodied the results in a second report. Again, in 1852, I studied in the same manner sixty-four cases of typhoid and typhus fever, which I had recorded since 1851, and the results were embodied in a third report. The whole number of cases analyzed thus were one hundred and sixty-four.

One advantage in studying these three collections of cases separately was, the results obtained from the collections severally could be brought into comparison with each other. The three reports were published in a volume in 1852. I may be permitted to refer to this volume for several reasons. It was my first-born of a bibliographical brood, which has since become somewhat numerous. It is not in a condition now to speak much for itself, as it has long been out of print. The edition was small, and, moreover, the volume was printed for the author, having only a nominal publisher, so that it never had a fair chance for much circulation. But it represents the employment of most of my leisure hours for a period of three years. Aside from the personal benefit derived from the studies, compensation for the labor was found in a remarkable correspondence with the results of Louis' researches as regards the clinical history of typhoid fever—a correspondence corroborating the accuracy of his researches, and going to show that the disease retains its historical characteristics in different countries and at different periods. I began the analytical studies with belief in the identity of typhus and typhoid fevers, but the studies converted me to the opposite opinion, and this opinion is now held by most, if not all, medical writers. In collecting my histories, I stumbled upon a number of cases of relapsing fever, and these were the only cases of this disease which, up to that time, had been reported in this country, except some recorded by Clymer, in 1846.

My subject to-day is the treatment of cases of typhoid fever by the antipyretic employment of cold water. I may mention the fact that, in my second report, I studied the effects of the wet-pack in five cases. By the "wet-pack" I mean enveloping the body in a wet sheet, and over it dry blankets, after the method of the so-called hydropathists of that time. This measure cannot act by the direct abstraction of heat; but it is entitled to be called an "antipyretic measure," for it is often followed by a considerable reduction of temperature. As such, it deserves more consideration than it appears to have received. Within late years I have known it to prove signally useful in many cases of febrile disease. When my reports were written, the thermometer had not come into clinical use, the intensity of fever being estimated by the subjective symptoms together with the sensation of heat communicated to the hand applied to the skin. The effect of the wet-pack, in my cases, was excellent; but I was deterred from continuing my observations by the occurrence of apoplectic coma in a case in which this measure had been employed with very marked immediate benefit. There was no ground for supposing that the treatment had anything to do with the occurrence of the coma; but, as the measure was then a novelty in medical practice, I considered that I would be held responsible for any accidents that might subsequently take place.

The following quotation from my second report expresses my ideas of the value of external refrigerating treatment at that time: "The direct effect of an increased disengagement of caloric, it is not improbable, may contribute to some of the evils of the febrile state. The most effective refrigerating measures, which possess much potency, are external applications, and these are *cold water* and *cool air*. Ablutions with cold water are usually grateful to the sensations of patients affected with fever, and abate, frequently in a striking manner, the increased heat and dryness. The simplicity of the measure causes it to be lightly esteemed by attendants, and sometimes, perhaps, by physicians. It is really an important part of the treatment of a large proportion of fever cases. The face, body, and extremities may be sponged, in succession, several times a day, or as often as the heat and dryness of the surface return. A faithful, judicious nurse may occupy a considerable portion of the time with these ablutions to the advantage of the patient. Should cold water occasion uncomfortable sensations (which is rarely the case), tepid or even warm water will secure, by evaporation, part of the refrigerating effect. The evaporation will be more rapid if spirit be added to the water. Cologne, or other perfumed spirits, may be employed for this purpose. Cold water, taken into the stomach, exerts a refrigerating effect on the skin and the system at large. Patients should be allowed to drink freely. The refrigerating effect of cool air is important. This is one of the useful ends of free ventilation. To secure this end, the patient should be lightly covered, and ventilation between the bedclothes attended to." These views, published thirty years ago, foreshadowed those which

at this moment hold the most prominent place in the treatment of fever.

Since the commencement of the session (1881–82), we have treated in this hospital [Bellevue] several cases of typhoid fever. In all the cases, except some in which the temperature of the body did not rise above 103° F., the reliance has been mainly on antipyretic measures, together with those of palliation and support. Antipyretic measures have been for several years mainly relied upon in treating the cases of this disease which have been received in the medical division of the hospital with which I am connected. The number of cases treated antipyretically is not large, being only fifteen.[1] These cases, however, have been observed closely, and the histories recorded with much painstaking on the part of the members of the house-staff who have had the cases in charge. During the whole, or the greater part, of the course of the disease, the temperature and the pulse have been noted every hour or two of the twenty-four hours in most of the cases. I propose, in this lecture, to give the results of the analytical study of these cases. I shall not challenge your patience by reading the histories. To do this would be intolerably tedious. From the histories I shall select the facts bearing on the following points of inquiry: (1.) The different modes of employing, externally, cold water, and the general rules observed in their employment. (2.) The antipyretic effect obtained, the time required, the duration of the effect, and the repetitions of the different modes of employing cold water for the reduction of temperature. (3.) The mortality and the duration of the disease in these cases. (4.) The employment of quinia as an antipyretic remedy in these cases. (5.) The employment of alcoholics. (6.) The dietetic treatment and the medicinal remedies employed.

1. *The different modes of employing externally cold water, and the general rules observed in their employment.*—In a few cases the cold bath was employed, that is, the patients were placed in a bathing-tub, in water of a temperature of 80° F., and the temperature reduced by the introduction of ice to about 65° F. This mode may be called, for the sake of distinction, the ice bath. It was soon discontinued on account of the inconveniences attending it, and it was not resumed because the employment of other modes appeared to secure all its advantages. The other modes were the sponge bath and the wet sheet with sprinkling. The sponge bath was often found to be notably effective. To obtain the utmost efficiency of this mode, the whole body exposed to the air is sponged with cold water, and the sponging continued steadily for a considerable time. As will be seen presently, the temperature of the body may, in many instances, be satisfactorily reduced by this mode. The wet sheet, however, is more effective. In carrying out efficiently the latter, the body is wrapped in a wet sheet, and sprinkling with water from a watering-pot, repeated at intervals of a few moments. The patient need not be removed from the bed if it be protected by a sufficiently large India-rubber cloth, but the cot known as "Kibbe's cot," is to be preferred. An ordinary cot-bedstead answers, however, very well. This mode of refrigeration is vastly more convenient than the bath-tub; it can be better regulated as regards the degree of cold, the duration of its employment, etc.; it is less likely to prove hurtful, and it may be made equally efficient. In most of the cases the sponge bath and the wet sheet were employed at different times during the progress of the disease.

The general rule with regard to the employment of these modes was to resort to one of them whenever the axillary temperature exceeded 103° F., and to continue it until the temperature was reduced to at least 102°. The temperature during the continuance of the employment of cold is, of course, to be taken in either the mouth or the rectum. The symptoms, aside from the temperature, were noted, and if at any time the pulse became feeble, the respiration disturbed, or the lips livid, the measure was at once discontinued. Alcoholics were often given during the continuance of the sponging or of the wet sheet with sprinkling. It will be seen that the wet sheet, in many instances, was continued for many consecutive hours.

2. *The antipyretic effect obtained, the time required, the duration of the effect, and the repetitions of the different modes of employing cold water for the reduction of temperature.*—In order to present as succinctly as possible the facts pertaining to these points of inquiry, which are contained in the histories of the cases severally, I have arranged them in a tabular form, and they will appear in a paper which I am preparing for publication in *The Medical News*.

I have found, on comparing these tables in respect of the number of repetitions of the employment of cold during the course of the disease, that they present notable differences. The number of ice baths given in all the cases was 5, of sponge baths 129, and of the applications of the wet sheet 64; the total number being 207; the number of repetitions of the sponge bath in one case not having been fully noted. Excluding the 4 fatal cases, the lowest number in any case was 3, the sponge bath having been employed once and the wet sheet twice in this case. In the case offering the next lowest number, 4 sponge baths were given; the highest number was 51, the ice bath having been employed 5 times and the sponge bath 46 times in this case. The next highest number was 18, this number of sponge baths having been employed. Now, the question arises, did the employment of cold in any of the cases have an agency in preventing permanently a rise of temperature, which would have occurred had cold not been employed? I think we may answer this question affirmatively; but much allowance is to be made for the differences to be observed in different cases of typhoid fever in the degree of fever-heat, irrespective of any treatment. Cases are not infrequent in which the temperature never rises above 103°. If, however, the temperature for a short time rise to 104° or 105°, and, after the employment of cold three or four times only, there is no further rise to 103°, it seems fair to attribute a certain amount of agency to the antipyretic treatment in preventing a subsequent degree of fever sufficient to call for a repetition of the treatment.

Notable differences in respect of the length of time required to produce an antipyretic effect are to be observed. The effect was produced by the ice bath in 30 minutes, by the wet sheet in 25 minutes, and by the sponge bath in 20 minutes. These were the shortest periods required; the longest were 20, 11, and 10 hours. Between these extremes, the length of time in the different cases varied much. This was true not alone in different cases, but at different times in the same case. It is evident that there are no known laws regulating the length of time required to produce an antipyretic effect. No judgment can be formed beforehand as regards this point; it can only be determined by experimental observation, and the result of the antipyretic treatment on one day is not to be relied upon in judging of the probable effect on other days during the course of the disease.

The statements just made respecting the length of time required to produce an antipyretic effect by the employment of cold, apply still more strongly to the production of this effect. Looking over the figures in the column devoted to this heading, it is found that variations were great. For example, in one case the

[1] It was subsequently ascertained that two additional cases had been overlooked.

consecutive durations are 10 days, 1 hour, 48 hours, and 24 hours. In another case consecutive durations are 2½, 13, 3, 20, and 5 hours. In another case, after consecutive durations of 6, 15, and 8 hours, the temperature before the last of these periods being 104°, there was no future rise to 103°. There is no approach to such a regularity in the successive periods during which the antipyretic effect continues as to point to any appreciable law. After the reduction of temperature has been effected, the previous experience, even in the same case, furnishes little ground for predicting the length of time during which the temperature will remain reduced. Nor is it practicable to judge beforehand, from either the duration of the antipyretic effect or its degree, of the amount of the rise of temperature which will take place. Nor, again, can any inference be drawn from the temperature which exists when cold is employed, whether or not hyperpyrexia will again occur.

In several instances a decline of temperature takes place after the discontinuance of the sponge bath or the wet sheet. The time during which the decline took place varied from 15 minutes to 15 hours. This fact was noted three times in one case, twice in two cases, and four times in one case. In one case the temperature was increased while the patient was in the wet sheet, reduction afterward taking place. So far as an inference is to be drawn from this collection of cases, it is not the rule, but the exception to the rule, for the temperature to decline after the discontinuance of either the sponge bath or the wet sheet.

It is not to be denied that the facts in these cases are not sufficient to test the relative value of the wet sheet and the sponge bath as contrasted with the ice bath. The latter was employed only five times and in only two cases. In each instance the temperature was promptly reduced. But there were instances in which the wet sheet and the sponge bath proved equally effective. The facts contained in the tables show that by means of the sponge bath a satisfactory antipyretic effect may be often obtained. This being the simplest mode and most easily employed, it may be first tried, and, if it fail, the wet sheet substituted. These two modes, singly or successively employed, will, as I believe, render unnecessary the use of the bath-tub. The wet sheet may be made more or less efficient, according to circumstances, by sprinkling at longer or shorter intervals and by using water of different temperatures.

Finally, I would call attention to the fact that in no instance could any immediate harm be attributed to either of the three modes of the employment of cold. In no instance were there symptoms following their employment so closely as to indicate that the patient had suffered injury therefrom. As a rule, the reduction of temperature was accompanied by improvement in other symptoms. Patients sometimes complained of discomfort, but this probably arose from the reluctance to be disturbed rather than from any unpleasant effects attributable to the cold; oftener they expressed a sense of comfort during its employment.

The number of cases in this collection is not sufficient for testing the influence of the antipyretic measures of treatment on the fatality from typhoid fever. In this regard, however, they may be considered as having some value. Of the fifteen cases, death took place in four. Two cases of recovery, in which the same measures of treatment were employed, were overlooked prior to the completion of the analytical study of the fifteen cases. Adding the two additional cases, the fatality was four in seventeen cases. This fatality is not far from the average rate in collections of cases otherwise treated. So far as any deduction is warrantable, it may be said that the antipyretic measures neither increased nor diminished the fatality.

The duration of the disease in the cases ending in recovery was determinable with precision in nine cases. The shortest duration was nine and the longest twenty-seven days. The mean duration was seventeen and a half days. The latter is one day and a half longer than the mean duration in forty-two cases analyzed by me thirty years ago. The commencement of the disease in the cases now and in those formerly analyzed was dated from the time of taking to the bed. In the cases now analyzed the fever was considered as having ended when the temperature had fallen to within the normal range, that is, from 98° to 99°.

It cannot be said that the mean duration in the cases now analyzed is evidence that the disease was shortened in its course by the antipyretic measures of treatment.

In the four fatal cases the shortest duration was fourteen and the longest thirty-four days. The mean duration was twenty-one and a quarter days. Post-mortem examinations were made in three of the four cases. In none of the three cases were grave complications found after death. Death took place in all by asthenia. In no case was there any ground for the belief that the antipyretic measures of treatment had any agency in the fatal termination.

3. *The use of Quinia as an Antipyretic Remedy.*—The sulphate of quinia was given in several instances, as an antipyretic remedy, in conjunction with the employment of cold. The instances are noted in the tables. How much effect may have been produced by the quinia in these instances cannot be determined with accuracy. Inasmuch, however, as the reduction of heat effected by the two was not greater or more rapid than often by cold alone, it is fair to conclude that the agency of the quinia was not great. In a few instances quinia was given for an antipyretic effect without being conjoined with cold. In one of these instances the temperature fell in eight hours from 103¼° to 102° after 30 grains of the sulphate of quinia. In another instance 20 grains were given, and two hours afterward 25 grains. In two hours after the last dose the temperature had fallen from 105° to 103¼°. In another instance 15 grains of the sulphate of quinia were given, the temperature being 104°. In five hours the temperature fell to 103¾°. Ten grains more were given, and in two hours the temperature was 102°. Ten grains more were given, and in two hours the temperature was 102¼°. A fourth dose of 10 grains was then given, and in four hours the temperature was 100½°. Ten grains three times were given on the following day, the temperature ranging from 100½° to 99°. These doses were continued during the next day, and the temperature rose to 102°. The patient was much cinchonised, and the remedy was discontinued. In another instance 20 grains of the sulphate of quinia were given, the temperature being 102¼°. In three hours the temperature had risen to 104°, and the wet sheet was then employed.

4. *The use of Alcoholics.*—In the treatment of these cases alcoholics were given to meet indications relating to the circulation. In some of the cases no alcoholics were given. The quantity given was regulated by the frequency and fulness of the pulse, and diminished intensity of the first sound of the heart as heard over the apex. Whiskey was the form generally used.

5. *The Dietetic Treatment.*—The chief article of diet during the course of the disease was milk. From one quart to two quarts were given daily, lime water being added.

6. *The Medicinal Treatment, exclusive of Quinia.*—In some of the cases no drugs whatever were given. Those which were given, exclusive of quinia, had reference to the palliation of certain symptoms. Digitalis was given in some instances for its tonic effect upon the heart, and ammonia as a cardiac stimulant. Opium

in small doses was sometimes given for diarrhœa. The medication was chiefly limited to these remedies.

From the study of these cases it may be concluded:

1. That by the employment of cold water externally in cases of typhoid fever, the temperature of the body may, after a variable time of the continuance of the employment, be reduced to 102° or lower.

2. After a period varying very much in different cases, and, also, at different times in the same case, the temperature, as a rule, again rises as high as, or higher than, before the reduction.

3. Repeating the employment of cold as often as the axillary temperature exceeds 103°, the number of repetitions required in different cases is extremely variable.

4. The sponge bath and the wet sheet with sprinkling may be employed to the exclusion of the bath-tub in the antipyretic treatment in cases of typhoid fever as well as of other febrile diseases.

5. These modes of employing cold water may be continued sufficiently long for the reduction of temperature to 102° or lower, and repeated as often as may be required, without risk of any immediate injury, and the study of these cases furnishes no ground for supposing that a liability to complications or accidents is thereby increased.

6. Reduction of temperature by these modes as often as it rises, in the axilla, above 103°, improves the condition of the patient. The cases now studied do not afford proof either that the fatality of typhoid fever, or that its duration is thereby diminished. The study of these cases, however, renders it possible that this proof would be afforded by a larger collection of cases.

During the period that the cases now studied were treated, seven hospital cases were recorded in which antipyretic treatment was not employed. In most of these cases the temperature did not rise above 103°, and it was for this reason that the treatment was not employed. Of these seven cases three were fatal, but I need not say that it would be unfair to draw any deduction from the contrast as regards the proportionate number of fatal cases. It is well known that, in general, resistance, toleration, and recuperation are not as well exemplified within as outside of hospitals. Moreover, in cases of typhoid fever, patients are not admitted into hospital until some days after the commencement of the disease. The clinical test of therapeutical measures, as far as fatality is concerned, is therefore best afforded by the study of cases in private practice.

7. The results of the analysis of these cases, although not sustaining the statements of Liebermeister and others respecting the controlling influence of the employment of cold externally in cases of typhoid fever, yet not only show this method of antipyretic treatment to be safe, but afford encouragement to employ it with the expectation of diminishing the severity of the disease and its danger to life.

ABSTRACT OF A CLINICAL LECTURE

ON THE RECOGNITION AND TREATMENT OF THE EARLY STAGES OF POTT'S DISEASE.

BY D. HAYES AGNEW, M. D.,

PROFESSOR OF SURGERY IN THE UNIVERSITY OF PENNSYLVANIA AND OF CLINICAL SURGERY IN THE UNIVERSITY HOSPITAL.

(Reported by J. WILLIAM WHITE, M. D.,

DEMONSTRATOR OF SURGERY IN THE UNIVERSITY.)

GENTLEMEN: There is, perhaps, no disease in which it is more important to recognize the early and premonitory symptoms than the one with which the little patient before you is affected, and which is variously known as Pott's disease, angular curvature, antero-posterior curvature, and caries of the spine. Each of these titles is in some respects objectionable. The name of Mr. Percival Pott has been associated with the disease because to him we owe the first correct exposition of its pathology and treatment. It, however, conveys no information as to the character of the ailment, and although the most common, is perhaps the least useful of its designations. Angular curvature and antero-posterior curvature are names derived from certain symptoms which are not invariably present, and which do not usually appear until what might be called the second stage has been reached. They therefore, as has been pointed out by Mr. Howard Marsh, are liable to mislead the practitioner by causing him to regard them as necessarily to be found at all periods of the disease. Neither is caries of the spine, although present in a large majority of cases, an absolutely constant pathological condition in such patients, the characteristic symptoms being sometimes produced by a process of interstitial absorption, which goes on to destruction of the bodies of the vertebræ without the ulceration and suppuration which are essential elements of true caries.

We may say, however, that, call it by what name you will, the disease is one in which, owing to one or the other of these processes, a disintegration of the vertebral bodies takes place, producing, *first*, irritation of the spinal nerves as they pass out through the intervertebral foramina, and, *second*, a crumbling of the affected bones under the superincumbent weight of the head and body. When this breaking down of the vertebræ occurs in the anterior portion of their bodies, as it commonly does, and when, as is also usually the case, it is attended with the production of pus, we have the more or less marked deformity, and the psoas, iliac, lumbar or dorsal abscesses, which, as a rule, characterize this period of the disease and render it easy of recognition.

I shall confine myself to-day, however, to calling your attention specially to the symptoms belonging to the first stage, which, in nearly every instance, are due to nerve irritation, and which, taken together, should almost unfailingly lead to the detection of the true nature of the malady, at a time when proper treatment will often result in complete cure without disfigurement, but which in practice I find are usually not recognized until this all-important period has passed. Any one of these symptoms may be the first to attract the attention of the child's family; but, as a rule, you will be consulted in reference to a supposed alteration in the little one's disposition, a tendency to avoid all active amusements, a slight dulness or peevishness, or general malaise, which only becomes noticeable or alarming on account of its persistence. If you will at this time carefully observe the movements and posture of the child, you will see that its motions are restrained, that it carries itself with unnatural stiffness, that its gait is possibly a little shuffling, the feet not being lifted from the ground, and that when standing or sitting it leans forward and rests its hands upon the knees or anterior portions of the thighs. You should now at once reflect that these symptoms are all explicable on the theory that some change is going on in the spinal column, probably in the vertebral bodies, but, possibly, in the intervertebral substance, which has set up an irritation in the spinal nerves, and has rendered them unduly sensitive; that, on account of this condition, play has become distasteful, as requiring muscular movement which produces at least a sense of discomfort; that the slight jarring or concussion of ordinary walking gives rise to pain; and that to remove pressure from the inflamed structures, the child, through the medium of its arms, instinctively transfers the weight of its head and shoulders to its lower extremities.

You then proceed to look for further symptoms of nerve irritation, and will, probably, by careful investigation, elicit some or all of the following:

Hurried or grunting respiration on slight exercise,

due to involvement of the nerves supplying the external respiratory muscles—serratus magnus, quadratus lumborum, intercostals, etc.

Pain in the shoulders, the walls of the thorax, or in the lumbar region, the seat varying with the portion of the spine affected by the disease.

Pain at the pit of the stomach, resembling an ordinary "belly-ache," but due to irritation of the spinal nerves, which, in common with the sympathetic, supply the intestines. This pain, like that of colic, is temporarily relieved by the prone position, pressure on the bowels controlling to a certain extent the irregular and spasmodic action of their muscular coats, which is associated with both these conditions, or, in other words, fulfilling the same function as the roller bandage in fractures.

Fidgety movements of the feet from implication of the crural or sciatic nerves, or their trunks of origin.

Pain in the hip, knee or thigh, due to the same cause.

Pain on jumping, coughing, sneezing or sudden turning, or on any movement which takes place while the dorsal muscles are relaxed, or, so to speak, "off guard."

Pain elicited by pressure upon the head or shoulders, and strictly localized, involving a small area directly over a definite part of the spine. Conversely, it will be found that the pain, if constant, will be relieved by placing the child in a prone position across the knees, and then separating them gently, so as to make traction in opposite directions upon the two extremities of his vertebral column.

Hyperæsthesia, also limited to a definite region, and detected by passing a hot sponge along the vertebral gutters. Evidences of pain are often manifested when the diseased part is reached.

Peculiar, and very characteristic, method of reaching objects lying upon the ground. The patient will lower himself not, as would be natural, by any movement of the body, which will be held rigidly perpendicular, but by flexing the knees and thighs until the hand touches the desired article. In rising, the same care will be observed to avoid flexion or rotation of the spine.

I do not desire to be understood as teaching that all of these symptoms are without exception present in the early stages of Pott's disease, but you may rest assured that in nearly every case you will find several of them, and that you will be able by their means to make your diagnosis and to apply your treatment.

The latter, both in principle and practice, is extremely simple. When you recall the condition upon which the symptoms depend, and remember that its progress is hastened and its severity increased by pressure and by the weight of the head and upper portion of the trunk, it at once becomes evident that surgical interference must be directed towards a removal of these sources of aggravation of the original trouble.

The recumbent posture, strictly adhered to and continued for a period long enough to permit of the gradual subsidence of the inflammation, the absorption of its purulent or cheesy products, and the development of new fibrous or bony material to consolidate and strengthen the affected vertebræ, would meet all the therapeutic indications. In young children this may be thoroughly carried out, the enforced rest only terminating with the occurrence of anchylosis, particularly if the disease be situated in the cervical or cervico-dorsal region. In the great majority of cases, however, this is hardly feasible; the natural restlessness of the child, and the absence of careful and continuous attention on the part of the parents, who see no marked external evidence of disease, usually sufficing to thwart this plan of treatment or to preclude its persistent employment. The same indications should then be met by the application of a mechanical apparatus, to be worn uninterruptedly, and which will permanently remove all weight from the inflamed bones.

Of all those which have been devised for this purpose, two only are worthy of mention, viz., the plaster-of-Paris jacket applied in the now well-known manner, or a leather jacket, accurately moulded and fitted over a plaster cast taken from the patient. The latter dressing, although more expensive at first, is lighter and more durable than the plaster, and answers the purpose of support equally well. With either of them, where the disease is situated above the lumbar region, the head-suspension apparatus becomes a necessary addition to the jacket. Both of these appliances act by shifting the weight of the head and shoulders from the spine to the irregular surface of the thorax, abdomen and loins and to the margin of the pelvis. When anchylosis has occurred, which may be known by a gradual disappearance of the symptoms, the jacket may be dispensed with, removing it at first for a few moments each day, and gradually lengthening the interval, until it is left off altogether. In conclusion, I would caution you against the common and harmful assumption that in every case some mechanical support can be employed, by means of which the patient can with safety be allowed to go about. In certain cases, fortunately not very numerous, where all these dressings give rise to pain, or in which the deformity appears and increases in spite of them, they should be withdrawn, the only possible hope of arrest or cure of the disease depending then upon strict and protracted recumbency. In conjunction with any of these plans of treatment, fresh air, sunlight, nutritious food, cod-liver oil, iodide of iron, and the phosphates constitute useful hygienic and therapeutic adjuvants.

ORIGINAL ARTICLES.

ON THE ERGOT TREATMENT OF DIABETES INSIPIDUS:

BY J. M. DACOSTA, M. D.,

PROFESSOR OF PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE AT JEFFERSON MEDICAL COLLEGE, PHILADELPHIA; PHYSICIAN TO PENNSYLVANIA HOSPITAL.

IN April, 1875, I communicated to the College of Physicians of Philadelphia[1] the details of a case of diabetes insipidus treated by ergot. So far as I know, this case was the first in which this agent had been systematically and successfully used. As attention was called to the matter, ergot has since been tried by a number of observers. My own experience with it, too, has been now comparatively large, and I think that altogether, from the lapse of time and the accumulating records, we are in a position to endeavor to determine its true value. I shall first narrate briefly some of my own cases. But of the first case, as it has been fully published in the Transactions of the College, I will only here say that I have seen the man of late years, and that he continues in excellent health. This is a record of case No. II.

CASE II.—A young man, twenty-one years of age, a patient in the Pennsylvania Hospital in 1877, of good family history, except that his mother died of consumption. He passed on an average ten pints of urine daily, of specific gravity 1005, of acid reaction, and without a trace of albumen or sugar. The disorder came on gradually, and, when he first noticed it, he was in excellent health. There was actually no cause to which it could be assigned, unless, perhaps, to work and worry,

[1] Transactions of College. Vol. I., 3d Series.

or to a doubtful history of a strain in lifting a heavy weight. He never had had venereal disease; he had received no injury to the head or spine; he had not had a sunstroke; there was no malarial history. His digestion was fairly good; the bowels were rather constipated; no disease of the heart, lungs, or any of the viscera could be discerned; the temperature was normal, or below the normal, 98°. He had lost flesh steadily and rapidly, and was strikingly emaciated when I saw him in the hospital, about six months after the outbreak of his malady. He complained of nothing but of debility, of a feeling of weakness in the small of the back, of the incessant urination, and of an irritability at the neck of the bladder, with a sense of burning, for which no adequate local cause could be discovered. He declared that he was not very thirsty, and that he passed more water than he drank. Unless he deceived us, such was indeed the case. We measured the fluids of every kind he took; they never exceeded six pints, and we cut them down to four pints; whereas, he passed not less than eight, and oftener ten pints in the twenty-four hours. He was very restless. There were occasionally chilly sensations and flushes of heat, and he was sometimes bathed in perspiration, but there were no night-sweats.

After observing his case, while he was taking no medicine and under varied diets, and finding it uninfluenced, he was placed on drachm doses of fluid extract of ergot three times, subsequently four times, daily, and for four days, six times daily. In a few days after the beginning of this treatment, he was no longer obliged to get up at night, and the pains had all left him; the flow had decidedly decreased. On the eleventh day he was noted to have greatly improved, and to have passed but five pints in the twenty-four hours. On the twenty-second day of treatment, he was voiding a little less than four pints of urine, and his whole condition was better. The ergot was reduced to a drachm three times daily. It had, throughout, not given him any inconvenience, unless a rather greater tendency to constipation was caused by it. This was met by the occasional administration of castor-oil. On the twenty-fifth day the ergot was still further reduced; he only got thirty minims thrice daily, and was discharging three and a half pints of urine, of almost normal specific gravity. On the thirtieth day the remedy was stopped and a little peppermint water given. He was passing but three pints of urine, while drinking five pints of fluids. His general condition was very good; but he was placed on cod-liver oil, under which he fattened and grew strong. An operation of phimosis was performed on him, which seemed to relieve the irritation of the bladder. He remained under observation in the hospital about three weeks after the ergot treatment was suspended; towards the last, taking nothing. The urine voided was about three pints daily, some days even a little less. He was discharged cured, in January, 1878, in fine health. As he has not reappeared, I think he has remained so.

CASE III.—A miner, admitted into the Pennsylvania Hospital September 29, 1876. There was an excellent family history, and the man himself had been in good health until the last few years; he never had had rheumatism or syphilis. In 1874, without assignable cause, he began to suffer from severe pain on the right side of the face and head, and the headache gradually became more continuous and localized in the right temple. There was never vertigo or vomiting, but loss of memory and irritability of temper; and the vision was much impaired, that of the right eye being lost. An expert, after his admission into the hospital, found blue atrophy of both optic nerves, complete on the right side. But besides the headache, the most annoying symptom was the discharge of about eighteen pints of urine daily, with considerable attending thirst, and a harsh, dry skin. The urine was clear, faintly acid, of specific gravity 1003, containing neither albumen nor sugar. There was no fever temperature. He was ordered one drachm of fluid extract of ergot three times daily; the urine, the next day, fell to fifteen pints. On the sixth day, the ergot was increased to two-drachm doses. In the course of a fortnight the urine had been reduced to four and a half pints, and the man had otherwise improved; he had less headache.

October 22, he complained, however, of severe frontal headache and dimness of vision; there was no increase of the urine. The ergot treatment was suspended, and ten grains of bromide of potassium given every second hour, with the subsequent addition of a few drops of deodorized tincture of opium. He was only passing two pints of urine. On the 27th, the urine had increased to five pints; he had still a good deal of headache, and restless nights. On November 1, he was observed to have a fever temperature, to be very excited and alarmed and delirious. The urine could not be measured, as it was passed involuntarily, but it was small in quantity. It was evident that he was suffering from an acute attack of meningitis superadded to previous disease. But as the case was made the subject of a clinical lecture, an abstract of which was published in the *Medical and Surgical Reporter* of January 6, 1877, it is unnecessary to go here into further details. It is only incumbent, for our present purposes, to state that the man was freely purged, and placed on iodide of potassium; that the acute symptoms lasted about two weeks, and that neither then, nor until his discharge, on December 6, did the urine become again of low specific gravity, or exceed four pints in the twenty-four hours, although the iodide of potassium was continued. Not only the acute symptoms, but the previous steady headache, greatly improved, and the man left the hospital apparently in good health, to return to his work.

CASE IV.—Joseph G., forty-two years of age, formerly a soldier in the U. S. Army, was admitted October 19, 1877, into the Pennsylvania Hospital. He had been in good health until three weeks before admission, when he had chilly sensations coming on every morning for a week, and lasting three hours. After continuing for a week, they terminated abruptly without medication; it is most unlikely that they were malarial. The temperature was 98.5° ranging to 99°; there was some œdema of the legs, but it was of short duration. He passed large quantities of urine, clear, acid, of specific gravity at first 1015, then less, and not containing either sugar or albumen; in amount the urine varied for the most part between five and a half and seven pints daily. A consolidation was found to exist at the right apex, associated with a moderate amount of cough. He took fluid extract of ergot, a drachm three times daily, for about a week, continuing an iron preparation on which he had been placed. But it produced no result, and as the temperature rose, reaching at one time 100.5°, and the signs of pulmonary consolidation at the apex became more manifest, his treatment was entirely altered. The temperature soon subsided again, and was for ten days lower than normal, ranging between 98° and 97.5°. At the end of this period, the urine was about five and a half pints daily; the chest symptoms were quiescent. He was placed upon full diet and strychnia; at first one-thirtieth of a grain three times daily, then one-fifteenth. In a week this treatment had no effect; in sixteen days he was passing but four pints daily, and was very much stronger and better. In about two weeks afterwards he was discharged at his own request, greatly improved; the signs of right-sided apex consolidation remained; the cough was very slight.

CASE V.—G. S. applied at the Jefferson Medical Col-

lege Clinic on the 23d of May, 1878, with excessive flow of urine. He was a dyspeptic, troubled with flatulency and occasional vertigo, and a feeling of soreness in the limbs and across the abdomen and the back. There was no cause to which the inordinate flow of urine could be directly traced; he stated that the weak back of which he complained, and his other symptoms, began with chilly sensations about a year before; but the flow of urine has been coming on for two years. He was found to have tubercular deposits, not extensive, at the apices of both lungs. It was impossible to get him to measure accurately the amount of urine passed in twenty-four hours; he kept a record of the night urine, and it was frequently eight pints. It was of low specific gravity, and contained neither sugar nor albumen.

The man was placed on fluid extract of ergot, half a drachm three times daily, which was subsequently increased, and he was directed to take nourishing food. In two weeks' time he had greatly improved, the soreness was entirely gone, and the quantity of urine largely decreased; how much he did not ascertain for us by measurement, but he was not obliged to rise at night nearly so often. On account of the dyspeptic symptoms, a mixture of five minims of tincture of nux vomica, ten of dilute phosphoric acid in compound infusion of gentian, was now administered three times daily, and the ergot no longer steadily used. He continued to do better and better until July 15, the urinary flow being no longer a prominent feature of his case, when he discontinued his visits. The lung affection had not increased.

CASE VI.—W. H. S., thirty years of age, applied at the Medical Clinic of the Jefferson Medical College, in October, 1879, on account of great weakness and excessive flow of urine. There was an old history of syphilis, a more recent one of severe malaria, contracted in the spring of 1878 in Texas, and which had broken out again in April of 1879. He was very pale and weak, had lost much flesh, and complained greatly of pains throughout the body, and especially through the limbs. But his chief disturbance was from the quantity of water he passed, some days not less than fourteen pints, six pints of which were voided at night. We made him measure the urine for three consecutive days; the record was eleven pints, ten pints, ten pints. This was on a varied diet; he had tried a restricted diet, such as a diabetic patient would employ, and no change was perceptible. The record of the three days alluded to was below his usual average. The urine was very pale, of specific gravity 1006, free from sugar or albumen. He was very thirsty, but thought he passed more fluid than he drank. The extreme flow had existed for a month. He was somewhat dyspeptic, with a tendency to constipation; the spleen was decidedly enlarged, the liver somewhat so, and he complained of tenderness over these organs, especially over the spleen. Just before he had malarial fever his horse fell on him, bruising his left side, since which time he has always had pain and some soreness there. Nothing else abnormal was discovered; the skin appeared to be acting fairly well. He was placed on a full diet and on ergotine, which, however, was soon exchanged for half a drachm of fluid extract of ergot three times daily. He did not improve; indeed, about a week after this treatment was begun, he passed, November 10, sixteen pints; 11th, eighteen pints; and in twelve hours of the 12th, twelve pints. An attempt was made to increase the dose of the fluid extract of ergot, but it did not suit his stomach, and we returned to the use of ergotine, in three-grain doses three times daily; while, for the constipation, an occasional pill at night was administered, consisting chiefly of small quantities of podophyllin and aloes. 13th, the urine was sixteen pints; 14th, twelve pints. This improvement slowly went on, and with it the man's general condition became better. 20th, lactate of iron was in addition prescribed. The urine on the 26th had been reduced to eight pints in the twenty-four hours, and at about this it remained until December 7, when the record was seven pints. The lactate of iron was now stopped, while the ergotine was continued, and gradually increased to six grains three times daily. A tonic mixture containing $\frac{1}{10}$th of a grain and 15 m. of tincture of the chloride of iron was also given three times daily; but from this, on the 21st, the strychnia was omitted. December 16, the record was five pints in the twenty-four hours; 21st, the same. The specific gravity rose with the decreasing quantity; diminution of the spleen was noted, and continued improvement in general health; the soreness and the pains had nearly gone. 31st, he passed four and a half pints; January 5, 1880, he felt himself well enough to go to work, still voiding that amount of urine, or some days a little more.

On the 15th, he reported that he was quite able to do his work, was gaining flesh, but that his appetite was failing, and that the bowels, notwithstanding occasional purgative pills, were costive. He thought the ergotine was disagreeing with him, and it and the iron mixture were stopped; the urine had not increased in quantity, nor returned to a low specific gravity. One-thirtieth of a grain of strychnia, with five minims of dilute muriatic acid in glycerine and water, was given three times daily, and the laxative pill already mentioned at bedtime. February 1, was gaining, the soreness of the limbs was nearly gone, the appetite was good; he passed four pints of urine daily, or rather less. A pill was required every night to ensure a movement the next morning. 14th, he reported continued improvement; for four days the amount of urine passed was not more than when he was in health, and he had discontinued measuring it; the strychnia was only given twice daily, the pill alternate nights. As the same favorable report continued March 1, with the addition of the statement that he felt as well as he ever had, the medicines were gradually abandoned. April 1, he was in as good condition as when last seen; the strychnia had been entirely stopped for a week; the laxative pill was taken every third or fourth day.

On June 14, after hard work, he had a slight relapse. The urine, which had remained normal in quantity, increased to eight pints in twenty-four hours; the tired feeling in the limbs returned. But the relapse was of short duration; it readily yielded to the former strychnia prescription, taken twice daily, and by the 20th he was again well. The strychnia was, however, continued for a month. August 1, 1880, he had not taken the remedy for two weeks; he remained well, and so he has until now.

When we look at these cases, we find five recoveries out of the six, and in two the patients have been since under observation, and it is positively known that the recovery from the disorder is lasting; of the other three, it is most likely that such is the result. In the case in which the treatment did not succeed, ergot was only tried, though in decided doses, for about a week, and, as it produced no effect, and there was a pulmonary complication, it was exchanged for strychnia, under which the patient did better, although not rapidly. The evidence of improvement in all in which improvement follows, is not only seen in the decreased flow of urine and its increased specific gravity, but in the better nutrition, the lessened thirst, the altered state of the skin, and in the subsidence of a symp-

tom to which I shall call particular attention, and which the analysis of these and others of my cases has impressed on my mind,—the pains in the limbs and body, and the feeling of soreness without tenderness. It is not my object to discuss here matters of general pathological and clinical import, but rather to bring forward the results of a special plan of treatment, or I should do more than merely touch upon this point; I should also do more than merely speak, in passing, of the connection with pulmonary disease, which two of the cases exhibited. In one there was a catarrhal pneumonia, in another a tubercular affection; and I have lying before me the notes of two others, the first of which, beginning with catarrhal pneumonia, I had the opportunity of following subsequently, to the autopsy, with pneumonic phthisis. Here the lung affection followed the polyuria. In the case described in this paper (Case V.) it was the same; at times the reverse appears true. There seems to be more than coincidence in the occurrence; and the matter, both with reference to chronic catarrhal pneumonia and phthisis, is well worthy of careful analytical study.

The treatment under discussion is not a difficult one to carry out. Here and there a stomach rebels, and the continuance in sufficient doses becomes impossible. Then, too, we may not be able to keep the ergot up long enough to effect the cure alone, though long enough to have practically broken up the disorder, for the urine does not again decidedly increase. Under such circumstances, as in Case VI., I have found strychnia an admirable remedy to follow the ergot treatment with, either as a permanent or temporary substitute; in other instances, wherever the ergot is continued, cod-liver oil becomes a good adjunct. The dose of ergot must be a decided one—at least one drachm of the fluid extract three times daily; better still, if well borne, twice that quantity. Case VI. took in place of ergot three grains of ergotine, increased to six thrice daily. But, on the whole, I prefer the ergot itself in extract. I have never seen any disagreeable consequences from the doses mentioned; never dilated pupils, markedly slower pulse or breathing, or vertigo. Some headache, and perhaps an aggravation of the existing constipation, are, besides any gastric disorder, the only unpleasant signs of the impression of the medicine. It takes generally about one week for it to show a decided influence.

As to the mode of its action, it is chiefly by the contraction of the capillaries; but where? in the kidneys or in parts of the nervous system, in ganglionic or cerebro-spinal nerve centres? Most likely in the centres. But our knowledge of the exact pathology of diabetes insipidus is too uncertain to speculate much on the manner in which a drug affects it. Then, too, there are classes of cases in which ergot is not likely to do much good; those, for instance, with a distinct cerebral lesion. But here, the character of the lesion will make much difference. Thus, in Case III., where it was probably meningeal to a great extent, the effect was very good. In degenerative diseases of the fourth ventricle, and brain tumors pressing there or elsewhere, ergot is not likely to be of benefit. But this is mere surmise; for we know nothing as yet from direct observation, as we do of cases of polyuria dependent on gummata cured by mercurial inunction[1] or by iodide of potassium. In instances of excessive flow of urine associated with renal disease, ergot only acts temporarily or not at all. We have at present under observation at the Pennsylvania Hospital, a man (August S., Men's Medical) who came in passing 225 ounces of highly albuminous urine. He has been voiding a large quantity for three years, with one decided intermission. At first he was dropsical, but this was early in the case, and before the excessive flow, which at one time reached 300 ounces. He is now passing 182 ounces after a two weeks' treatment with ergot, increased gradually to half a drachm of the fluid extract of ergot eight times daily; belladonna did no better.

Ergot has been in the last few years tested by others than myself, and I shall analyze such of the recorded cases as I have met with. Dr. Tyson[2] publishes a failure. The drug was given in sufficient doses, one drachm of the fluid extract three times daily, increased to two drachms. It answered well for a short time, but not permanently, and its use was exchanged for gallic acid, which did better, although it is not known whether the improvement was sustained. On the other hand, ergot has been successfully employed by Sydney Ringer, Murrell, Rendu, Saunders, and McClellan.

Sydney Ringer's case[3] was a very marked one of the disease. It happened in a man thirty-eight years of age, of temperate habits, in whose family there had been many cases of consumption. The quantity of urine varied from 9 to 22 pints. The patient was much troubled with thirst, loss of appetite, dry skin, and constipation. The disease was uninfluenced by quinia, cod-liver oil or jaborandi. But on three occasions the quantity of urine was greatly reduced by ergot. Thirty minims of the liquid extract every third hour, was the dose last employed. The urine was in twenty-four days brought down to a pint and a half daily. The man has been seen after the lapse of four and a half years,[4] the urine is normal in quantity, and he is strong and well.

In a case reported by Murrell,[5] the patient, a lad, had first taken belladonna with advantage, but without a permanent result. He was subsequently placed on ergot in aggregate daily doses of two drachms, kept up fully for a month, the quantity of urine falling from 3174 cubic centimetres to from 1700 to 1983 c. c. daily. The patient ultimately died from hemorrhages away from the hospital, and after a prostrating sea voyage. The improvement in the urinary secretion, it was thought, was permanent.

Rendu[6] details a case of polyuria cured by the administration of powdered ergot, at first given in doses of 50 centigrammes for six days, and sub-

sequently of a gramme. The affection followed a fall into the sea. Valerian had been found to be useless, and atropia did not suit, and was soon discontinued.

Saunders[1] has given us the history of a woman fifty-three years of age, who became so enfeebled by the excessive flow of urine, from sixteen to twenty pints in the twenty-four hours, and the constant thirst, that she was unable to attend to her household duties; the skin was dry and harsh, the bowels excessively constipated. She suffered greatly from pains in the back and side, and had been ailing for two years. Fluid extract of ergot, one drachm three times a day, reduced the urine so rapidly that it alarmed her. The remedy was kept up for two or three months; a few relapses being occasioned by its unauthorized discontinuance. A perfect recovery took place, and when last seen, she had been in excellent health for months.

Surgeon Ely McClellan,[2] U. S. A., treated a case successfully with ergot that had been uninfluenced by full doses of quinia. It was only of some weeks' standing when seen; but the patient passed from twenty to twenty-four pints of urine daily, of specific gravity of 1008, and the inclination to urinate was at night so urgent that he was almost deprived of sleep. Inordinate thirst, impaired appetite, and serious constipation were also very troublesome symptoms. Fluid extract of ergot, in half drachm doses, was administered every four hours. At the end of the first week, the amount of urine had sensibly diminished; at the end of the second week, it was reduced to one-half, and the thirst had almost disappeared. The remedy was then given three times daily for two weeks longer, when all the symptoms disappeared. Seven months after treatment had been suspended, the man remained well, passing forty-seven ounces of urine daily, of specific gravity, 1020.

On the whole, then, ergot makes good its claim to confidence in the treatment of diabetes insipidus. That it always succeeds, even when faithfully used, will not happen. But it is pleasant to be able to confront the statement of so recent and distinguished a writer as Senator,[3] that "the prognosis of diabetes insipidus is, in respect to recovery, very doubtful," with the array of cases here brought together.

EXTIRPATION OF THE LEFT KIDNEY ON ACCOUNT OF A LARGE FIBRO-CYSTIC TUMOR—RECOVERY.

BY T. GAILLARD THOMAS, M.D.,
SURGEON TO THE NEW YORK STATE WOMAN'S HOSPITAL.

IT may now be safely assumed that the operation of nephrectomy, or extirpation of the kidney, is one of the recognized and legitimate procedures of surgery. That this operation is one of necessity, and that without a resort to it, lives which by it could be saved, would necessarily be lost, no one can doubt who examines, even in the most cursory manner, the literature pertaining to the subject.

Fifty-seven cases are now on record, or rather that which I now relate makes this number complete, and from this array certain conclusions may be drawn as to the wisdom of resorting to the procedure, and the propriety of considering it one of the legitimate resources of the surgical art.

Mr. A. E. Barker,[1] writing in April of this year, declares that the number of cases on record up to that time was 54; that of these 26 recovered and 28 died; that lumbar operations show rather better results than those through the abdomen; and that in 11 out of the 54 cases, over one-fourth of all reported, an incorrect diagnosis had been made.

H. Braun,[2] writing in August, cites 56 operations. Of these 28 were laparotomies, with a result of 18 deaths and 10 recoveries; and 28 were lumbar sections, with 9 deaths and 19 recoveries.

The pathological conditions which have heretofore called for the operation, have been neoplastic growths, such as cysts, fibro-cysts, and sarcomas; cancerous disease; floating kidney; calculus; hydronephrosis; tuberculous kidney; and fistulous connection between the ureter and the uterus, or vagina.

It has repeatedly been performed upon very young children; for example, by Czerny upon a child eleven months old, by Kocher upon one two and a half years old, by Jessop upon one of the same age, by Hüter upon one of four years, and by Thornton upon one of seven years. Of these only two cases recovered, Jessop's and Thornton's.

I now proceed to give the history of the case which has called forth this paper.

Mary P., a native of Germany, 21 years of age, a pale and rather delicate person, was admitted to my service in the Woman's Hospital, October 13, 1881. Upon examining her I found in the abdomen a soft and obscurely fluctuating tumor, about as large as the uterus at the eighth month of utero-gestation. This was centrally placed, fell well down into the pelvic cavity, was perfectly movable, and was not tender upon pressure. The patient gave evidence of no special or peculiar symptoms, except that of very severe and constant pain in the abdomen. Her suffering was so great that she declared that she could no longer tolerate the tumor, and must have it removed. I saw no reason to suppose the tumor to be other than ovarian, and arranged for ovariotomy on the 15th of October, the patient being at once put upon preparatory treatment.

The operation was performed on October 15. As soon as the abdominal walls and peritoneum were cut through, I passed in my finger, discovered between the tumor and the symphysis pubis a large coil of intestine, and at once felt convinced that the growth was not of ovarian origin, though as yet no suspicion of its real nature entered my mind.

There was so much solid material about it that I had to enlarge my incision before I could puncture with the trocar. When I did so, six pounds of an amber-colored fluid poured away, the appearance of which led me to ask an assistant who was collecting some of it in a vial for examination, whether it was

[1] Lancet, April, 1881.
[2] Deutsche Med. Wochenschrift, 31, p. 421, August, 1881.

not urine. Now for the first time the thought of hydronephrosis presented itself to my mind. It was found, however, not to be urine.

I found the tumor everywhere adherent, and recognized the fact that to remove it, it would be necessary for me to tear it out of its bed. As I proceeded, a large number of ligatures became necessary, and a good deal of blood was lost.

Professor A. C. Post now suggested that a mass at the upper extremity of the tumor looked like the kidney, and, upon examination of this, it was found to be so. I now included all the emulgent vessels and the ureter in one ligature, severed the mass, and dropped the ligated portion back into the abdominal cavity.

The patient was then put to bed, and the ordinary treatment after ovariotomy was ordered. For the first three or four days she suffered such severe pain at the epigastrium that morphia had to be used hypodermically very freely for its control, and the temperature showed a tendency to rise. As the importance of the case, however, calls for a day to day history, I avail myself of the notes of the house surgeon of the hospital, Dr. Andrew F. Currier, to whose assiduous and intelligent care I feel greatly indebted.

On the 16th, at noon, the temperature was 102°, but by the douche, applied after Kibbee's method, which I invariably employ after ovariotomy when the temperature becomes exaggerated, it was reduced to 100½°. The pulse during this day ranged at about 100.

On the 17th, the morning temperature was 102½°; the evening, 100½°, being kept down by the douche. Pulse, same as yesterday.

18th, morning temperature, 100°; evening temperature, 101¾°. Pulse ranged at about 100.

19th, A.M., 100°; P.M., 101°. 20th, A.M., 100⅕°; P.M., 99¼°. 21st, A.M., 99¾°; P.M., 101°. 22d, A.M., 99¾°; P.M., 101°.

After this the patient progressed very favorably, and, with the exception of a mural abscess, presented no troublesome symptom, and at the present date, one month from the time of operation, she is up and fully convalescent.

The gross appearances of the tumor were these. The whole mass, fluid and solid, weighed 10½ pounds. The tumor growing from the capsule of the kidney on the convex surface of the organ, bent it over backwards so as to make this surface concave, and to render the portion on which was the hilus convex. The structure of the kidney appeared to the naked eye entirely healthy.

The tumor was submitted for examination to Dr. Welch, the pathologist of the hospital, and the following is his report of it:

"That portion of the kidney to which the tumor was attached was not sent to me, nor did I receive any of the fluid from the main cyst. The remainder of the kidney, and the greater part of the tumor, however, came into my hands.

"The growth is partly solid and partly cystic. The solid part is said to have weighed, when removed, 4½ pounds, and the fluid 6 pounds. There is a main cyst, the size of which about equals that of a child's head. A part of the wall of this cyst has been removed, and was said to be closely adherent to the kidney. The rest of the tumor consists in greatest part of dense, white, glistening tissue, in which appear many cysts, varying in size from a pea to a hen's egg.

"In the dense stroma there are also many patches presenting a yellowish, translucent, gelatinous appearance, and composed of a wide-meshed tissue, infiltrated with serous-looking fluid. These œdematous-looking patches resemble the so-called geodes of the fibro-cystic tumor of the uterus, and from these geodes can be clearly traced the development of the cysts.

"The fluid contained in these cysts is of a yellowish or reddish-yellow color, and spontaneously coagulable. Whitish coagula were found floating in the fluid of all the cysts opened. The microscopical examination of the fluid showed the coagula to consist of finely fibrillated fibrin, and, in addition, revealed the presence of leucocytes and red blood-corpuscles in moderate numbers. (Unfortunately, I am not able to report the characters of the fluid in the main cyst.)

"The dense stroma, of which the solid part of the tumor is mainly composed, consists of fibrillated connective tissue containing branched cells. The fibrillated basement substance in most places preponderates over the cells.

"In the gelatinous patches (geodes) the fibrils of connective tissue form a loosely interlacing meshwork, containing serum and numerous leucocytes, with some branching cells. The appearance is that of mucoid tissue, but no reaction for mucin could be obtained with acetic acid. In the development of the cysts, the tissue in these patches acquires a looser and looser texture, the meshes become wider and wider, the interstitial fluid increases in amount, until a cavity with smooth or slightly vigorous walls is formed.

"The walls of the cyst are not lined by epithelium, but simply by the surrounding connective tissue.

"The exterior of the tumor presents a somewhat lobulated appearance, and is apparently covered over a part of its extent by peritoneum.

"The tumor is to be regarded as a fibroma in which cysts have developed, either by mucoid metamorphosis of the fibrous tissue, or by distention of the interstices of the connective tissue by lymph."

USE OF PLASTER-OF-PARIS IN THE TREATMENT OF CLUB-FOOT.

BY P. S. CONNER, M.D.,

PROF. OF ANATOMY AND CLINICAL SURGERY, MEDICAL COLLEGE OF OHIO.

THAT the deformity of club-foot may be corrected, it is necessary (1) that the distorted parts be put in normal position, and (2), that they be kept there; and, just in proportion as any plan of treatment accomplishes these indications, it is a proper one to be employed. Every one knows that in the great majority of congenital cases it is possible, during a variable but quite considerable time after birth, by

manipulation, to bring the foot into its natural place; and, could it be sufficiently long and steadily held there by the hand of parent or nurse, rectification of the deformity would almost to a certainty result. What can be substituted for such gentle yet efficient hand-pressure? Ordinary bandages and adhesive plaster strips have been employed, and, in many cases, with advantage; but not infrequently they have been found insufficient, and the adhesive strips often very much irritate the delicate skin of the foot and leg. As a rule, club-foot apparatus are not applied until the child is a few or several years old, when the deformity has become quite well developed, and when frequently strongly contractured tendons and more or less altered joint-surfaces much complicate the case. Against all the forms of these mechanical appliances several objections lie. In the first place, oftentimes they are badly adjusted, and in the majority of instances they do not maintain the correction made when they are applied; next, making pressure generally upon only a limited number of points, their use is very apt to be followed by local irritations, with resulting ulcers or callosities; again, they are expensive, and often require much repairing, and very many club-foot patients are the children of poor parents.

Recognizing the existence of these disadvantages, I have, for several years past, been experimenting with the plaster-of-Paris, recommended long ago by Little; the youngest subject upon which it has been applied being two weeks old. The success which has attended these experiments leads me to believe that this method of treatment may, in many cases at least, be advantageously employed. The application of it is easy; an ordinary plaster roller being turned over the foot, ankle, and the lower half of the leg. In quite young patients a layer of cotton may with advantage be laid on, and the bandage put over it; in older ones the latter should be placed directly on the skin. The thickness of the covering must of course vary with the amount of deformity and existing muscular power. Before the plaster begins to set, the foot is to be brought as near its normal position as can be done without causing any decided pain, and held in place until the hardening is complete. Great care must be taken not to attempt too much at first. Preliminary tenotomy is to be made or not, according to circumstances, but is seldom required in young subjects. At each subsequent dressing more and more rectification is to be effected. Removal of the bandage will be required ordinarily in from three to six weeks, and the treatment, so far as I have been able to determine, must be continued for from six to eighteen months, and afterwards either a half boot with stiffened sides or the usual club-foot shoe worn, the former being generally sufficient to prevent any reproduction of the deformity.

Two objections have been made to this method of treatment; first, that the dressing is a heavy and clumsy one, and second, that the proper development of the foot will be prevented. If properly applied, the weight of the plaster bandage is not so great as to prevent ready use of the limb if the patient is old enough to run about; and I have yet to see a single case in which the growth of the foot has been interfered with, or in which flattening of the arch has been produced. The advantages of the method are, that it is efficient, cheap, distributes the pressure which must be made in order that the foot shall be brought round and kept in place, can be employed at a very early period, can be put in practice by any one of ordinary skill and judgment, and does not necessitate calling in the aid of the surgical instrument maker, to whom oftentimes the case is turned over with instructions to "put on a club-foot shoe," as though it was to be treated simply with leather and steel. If it be thought advisable to have the foot daily bathed and rubbed, instead of the plaster roller, the "Bavarian" dressing might be applied; but I have never used it, preferring that the pressure should be continuous for as long a period as possible, with only such intermissions as are absolutely required for the reapplication of the bandage. When the deformity is of long standing, and large callosities are present from pressure, either of a previously-worn shoe, or of the weight of the body in standing and walking, special care must be taken in applying the dressing, and rectification must be very gradually brought about; otherwise ulceration will occur, and, as a consequence, the treatment may, and probably will, have to be entirely suspended until the ulcer heals, and, as generally happens under such circumstances, whatever the method pursued, the malposition will rapidly be reproduced.

HOSPITAL NOTES.

ON THE TREATMENT OF FRACTURES OF THE UPPER EXTREMITIES, IN THE BOSTON HOSPITALS.

(*Specially reported for* THE MEDICAL NEWS.)

IN general, it may be said that plaster or other immovable dressings are almost never used in the treatment of *fresh* fractures in the Boston hospitals. Stiff bandages of either plaster, silicate of potash, starch and glue, or dextrine, are, however, applied in a large majority of cases later on in the treatment, when the union of the fragments has become somewhat firm, and the swelling has subsided. Ether is given when reducing fractures of the thigh, and in other cases where there is difficulty in overcoming the displacement of the fragments, or in making an accurate diagnosis.

Simple fractures of the humerus, in its upper third, are treated by means of a shoulder-cap, made either of wire, gutta-percha, felt, or two layers of rather coarse gauze, with plaster well rubbed into it. This is moulded to fit the shoulder, a pad is placed in the axilla, coaptation splints are applied to the inside, back, and front of the arm, and the wrist is placed in a sling.

Simple fractures of the middle third are treated by a shoulder-cap extending well down towards the elbow, coaptation splints, and a sling for the wrist. Sometimes, in addition to the above, an internal angular splint is applied to the elbow.

Simple fractures of the lower third are put up on an internal angular splint; and this splint is also used for all fractures about the elbow, whether above, through, or below the joint, except those of the olecranon.

Dr. Ingalls, of the Boston City Hospital, is of the opinion that, in many cases of fracture of the humerus near the elbow joint, the best treatment is to make traction with the arm extended, instead of being flexed around an internal angular splint; and he intends to

treat these fractures in the above manner, and to pay particular attention to the use of passive motion as early as possible.

In cases where there is shortening, which cannot be controlled by the ordinary appliances, extension by a weight attached to the lower fragment, and counter-extension by means of elastic bands attached to the upper, passed across the body and fastened to the bed, is often employed.

In fractures high up, where there is displacement forwards, the side of the thorax may be used as a splint by placing a small pad in the axilla, coaptation splints around the arm, and over these a firm, well-starched Velpeau bandage. In this manner all leverage upon the lower fragment by the movements of the forearm is avoided. Instead of the Velpeau, a many-tailed bandage, the ends of which pass round to the opposite side of the body and are there tied, may be used.

Compound fractures of the humerus.—Where the external wound is small, it is sealed with lint soaked in compound tincture of benzoin, or carbolic oil; where it is more serious, it is thoroughly washed out with a solution of carbolic acid and done up in a "Lister dressing," carbolized cotton batting dressing, "Phenyl dressing,"[1] or constant irrigation with a carbolic solution is used. The above treatment is the one used in all compound fractures, whether of the upper or lower extremity.

In cases where the external wound is but slight, splints similar to those used in simple fractures are applied at once. Where the wound is more extensive, the arm, done up in one of the dressings mentioned above, is in many cases placed in a tin tray, or one made of gauze and plaster, and packed around with oakum, or carbolic gauze; and the wound is kept as far as possible in an antiseptic condition. As soon as the condition of the wound is such as to allow of more active treatment, splints of various shapes, which will as far as possible admit of the wound being dressed without necessitating their removal, are applied.

COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

(*Clinic for Diseases of the Throat.*)

CASES OF RARE CONGENITAL DEFORMITY OF THE POSTERIOR NARES AND THROAT.

(Under the care of PROF. GEO. M. LEFFERTS.)

CASE I. *Double Septum.*—The following curious abnormality was only discovered by accident during the rhinoscopic examination of a young man æt. 25, who had applied for treatment for a chronic catarrhal pharyngo-laryngitis. The posterior edge of the *septum narium*, from its point of mergence into the parts making up the vault of the pharynx to one half way in its course from the floor of the nares, was divided vertically into two distinct halves, enclosing between them a space large enough to contain perhaps the end of a lead pencil. This space was more or less triangular in shape, its base lying above, and was lined apparently with normal mucous membrane. Its depth was not ascertained, but an anterior examination of the nasal passages disclosed nothing abnormal as to the configuration of the septum. There was no history of injury to the nose or skull. No symptoms were referable to the condition, and its presence was of course unknown to the patient.

CASE II. *Congenital Lateral Deficiencies of Velum.*—A girl, æt. 19, in attendance upon the clinic for the treatment of an ordinary catarrhal affection of the throat, has, through the *velum palati*, to either side and just above the point where the anterior pillar of the fauces loses itself in the broad expanse of the soft palate, a symmetrical, ovoid perforation the size of a small pea. The edges of these openings are smooth and rounded, are free from all cicatricial tissue, as are the parts in the immediate neighborhood, and are soft and lax. The patient has never had ulcerated sore throat nor indeed any severe affection of the parts, and remembers that the openings here described have always existed without change, a statement that is corroborated by her mother. The condition gives rise to no inconvenience, and demands no surgical interference.

Remarks.—The rarity of such instances as are here reported renders them of interest. They are, however, to be regarded as curiosities, and as of little practical import, except in so far as the recognition of their possible occurrence will guard against diagnostic errors. I know of but one case recorded in literature similar to the first described (Schrœtter, *Laryngologische Mittheilungen*, Wien, 1875), and of none similar to the second. Langer, in a series of investigations of embryological sphenoid bones, suggested by the case just alluded to, found that a canal exists between the two halves of the sphenoid during the first months of fœtal life, and rightly, I believe, classes such cases as the one that I have described as being due to an arrested development.

The same explanation probably holds good for the second case, but is not so readily demonstrable; indeed, the very seat of the lesion, away from the median line, militates to a certain extent against the hypothesis. No other, however, suggests itself for this particular and peculiar deformity occurring in this locality.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

Service of D. HAYES AGNEW, M.D.

A POSSIBLE COMPLICATION IN LITHOTOMY.

(Reported by J. WILLIAM WHITE, M.D.)

DURING a recent clinical lecture, Dr. Agnew, who was about to perform lithotomy, called attention to a temporary condition of the patient which necessitated delay. Etherization was complete, but the respiratory movements were hurried and excessive; the sphincters of the anus were entirely relaxed, and the anal aperture was patulous, an inch and a half or two inches in diameter, and moving in sympathy with the expansion and contraction of the thorax. In this manner it seemed to act as a valve, admitting air to the rectum, but not favoring its expulsion, so that for several minutes the lower bowel was in a state of distention. Of course, there would have been great danger of wounding it if the operation had been proceeded with under these circumstances. In a short time, however, as deeper anæsthesia was produced, the anus resumed its normal appearance, and the rectal dilatation disappeared. So far as we know, this possible complication of lithotomy has not been alluded to.

JEFFERSON MEDICAL COLLEGE HOSPITAL.

CASES OF REMOVAL OF THE BREAST FOR CARCINOMA.

(Under the care of DR. SAMUEL W. GROSS.)

IN carcinoma, Dr. S. W. Gross makes it an invariable rule to remove not only the entire breast, but its investing skin, connective tissue, and fat, the fascia of the pectoral muscle, and the axillary glands. If the muscles are involved, the nodules are unsparingly excised, and the apparently sound parts touched with the actual cautery or a strong solution of chloride of zinc. Even when the glands in the axilla are not palpable prior to operation, that cavity is always opened and thoroughly explored with the finger, since in not a few instances incipient glandular involvement is detected in this way.

In dealing with the glands, if they have served as sources of infection of the surrounding tissues, through which they are matted together and form a confused mass, the contents of the axilla are removed by a formal dissection, care being taken to pass a catgut ligature around the vessels before they are divided. When, on the other hand, the disease is limited to the glands, and the carcinomatous structure is contained within their capsules, they are simply enucleated by the finger, or a pair of scissors curved on the flat. When there is much oozing from the pectoral muscle, the hæmorrhage is readily restrained by the application of napkins wrung out of hot water. The entire wound is then washed with a two per cent. solution of carbolic acid; a drainage tube is inserted into the axilla; the wound is closed as accurately as possible by sutures inserted some distance from its edges; and lint imbued with carbolized cosmoline, confined by a broad flannel roller, finishes the dressing. Conducted in this way, Dr. Gross believes that a certain proportion of cures follow the operation; an assumption which is verified by Case III. The scar left by such thorough removal of the tissues is remarkably small. In Cases II. and III., it was not over an inch in width, and it was soft and pliable. In Case I., the large wound was reduced, by the insertion of sutures and the application of adhesive strips, to an area one-third less than that of the palm of the hand.

CASE I. *Scirrhus of the Breast, Skin, and Axillary Glands—Thorough Removal of the Affected Structures.*—A robust, healthy-looking woman, forty-two years of age, the mother of nine children, first noticed, twenty-four months ago, a small lump above the right nipple. The latter began to retract at the expiration of one year; and at the same time nodules appeared in the skin, the largest of which, an inch in diameter, was situated near the mammilla, and the others, to the number of seven, occupied the upper and sternal borders of the heart. At the expiration of sixteen months, she noticed lumps in the axilla, which now formed a dense elongated mass in that cavity. There were no antecedents, nor was there pain in the upper end of the humerus on pressure. The entire organ, with its investments, and the pectoral fascia, was removed by a circular incision; the axilla was opened by a cut, which extended from the upper and outer side of the pectoral incision, and the diseased mass of glands, fat, and connective tissue were dissected out, seven vessels requiring ligation. The temperature rose to 100⅘°, and the pulse to 120, on the following morning; after which they gradually fell, and became normal on the morning of the fourth day. At the expiration of two weeks, when the granulations had reached the level of the surrounding skin, twelve epidermic grafts were inserted, and, when we saw the patient two days later, ten had taken.

CASE II. *Recurrent Scirrhus in the Axilla—Thorough Removal.*—A married, healthy woman, fifty years of age, was subjected to amputation of the entire breast (which was ulcerated, but mobile on the chest, and in the investing skin of which, towards its sternal border, there was a small carcinomatous nodule), and excision of infected axillary glands, on the 23d of October, 1880. On the 16th of November, 1881, the cicatrice was soft, pliable, and not over an inch in width; but a gland on the side of the chest, at the termination of the cicatrice, and a mass of glands in the axilla, were readily detected, of the existence of which she had no knowledge. Dr. Gross made a clean dissection of the axilla, removing a mass of glands and infiltrated tissues, along with an enlarged gland beneath the lower border of the pectoralis major muscle, a few of the fibres of which were also excised. Six vessels, including the subscapular artery and vein, were tied.

CASE III. *Scirrhus of the Breast and Axillary Glands—Thorough Removal—Permanent Recovery.*—On the 4th of September, 1878, Dr. Gross amputated the entire breast, and cleaned out the axilla of a single woman, forty-eight years of age. The tumor was of twelve months' duration, and as large as a small lemon; the nipple was retracted, and the skin was adherent. At the end of six weeks the entire wound had closed, and the woman has since performed her duties as a laundry maid with perfect comfort. The cicatrice is soft and mobile, of a natural tint, and hardly an inch in width, and there is not the least sign of recurrence in the axilla. Thirty-eight months and a half have now elapsed since the operation, and Dr. Gross has every reason for assuming that the result is final.

MEDICAL PROGRESS.

TREATMENT OF EPITHELIOMA OF THE NECK OF THE UTERUS.—Dr. CHÉRON, referring to the Italian experiences with this practice, employs the nitrate of lead in ulcerating epithelioma of the uterine neck. After cleansing the surface with charpie moistened with glycerin, or washing out the canal with perchloride of iron solution if there is much oozing of blood, he applies to the ulcerated surface with an insufflator the following powder: Plumbi nitrat. purif. ʒi. Lycopodii ʒij. The powder is kept in position by a suitable tampon. Under the action of this preparation the suppuration diminishes sensibly and the odor disappears. The hæmorrhages are also suppressed. After twelve or fifteen of these applications, the engorgement of the cul-dè-sac diminishes, and the general health is greatly improved.—*Journal de Thérapeutique*, October 10, 1881.

A NEW THEORY OF URÆMIA.—MM. FELTZ and RITTER have recently announced that the real cause of uræmia is a change in the proportional quantity of potassa in the blood. The amount of the potassic salts in the blood, as in the urine, varies with the quantity and quality of the food. A special alimentation, in which the sodic salts preponderate, long continued, has the same effect on the quantity of the salts of potassium, as a poor and insufficient diet. The quantity of the salts of potassium contained in the blood influences in a certain degree the amount of urea necessary to produce grave or fatal results. Suppression of the renal function by the simultaneous ligation of the ureters determines in the blood and in the serum a sensible increase in the potassic salts except the supplementary gastro-intestinal excretion. In this respect the alkaline salts obey the same law as urea and extractive matters, which increase in the blood under the same conditions. The most serious results of experimental uræmia are not connected with the retention and accumulation in the blood of the urea or extractive matters of the urine, but, on the contrary, are produced by the injection of fresh, normal urine, or of equivalent solutions of the salts of potassium in distilled water. We think it must be admitted that the real agents of the toxæmia are the salts of potassium which accumulate in the blood.—*Bull. Gén. de Thérap.*, September 15, 1881.

THE TREATMENT OF TYPHOID FEVER BY ANTIZYMOTICS.—Dr. PECHOLIER, *Agrégé* of the Montpelier Faculty of Medicine, writes to the *Bulletin Gén. de Thérapeutique*, for September 15, 1881, on this topic. It is well known, he says, that creosote or phenic acid is absolutely opposed to all fermentation. Recognizing that typhoid fever is produced by a special ferment, he concluded to attempt the arrest of the pathological fermentation by the administration of antizymotic remedies, so long ago as 1868, and he therefore claims priority in

this mode of practice. MM. Desplats, Hallopeau, and Raymond, have ascertained by the graphic method the antipyretic action of the antizymotics. The special fermentation, which is the initial phenomenon of typhoid, is accompanied by the production of heat, as is the case in all kinds of fermentation. It is by suspending or moderating this fermentation, that creosote or phenic acid lowers the thermic curve. Large doses, he holds, are not necessary, and there is the danger in their use of exciting gastro-enteric irritation. When he finds prolonged administration necessary, he gives the remedy by rectal injection—10 drops in 150 grammes of water (about 5 ounces). The injections have, he thinks, a useful detergent and disinfecting action. This practice is not incompatible with the methods of hydrotherapy, but reserving cold baths for special cases, he generally employs tepid baths of 82½° to 91½° F., but he does not the less continue his practice of combating typhoid fermentation by the measure above mentioned. Proceeding in this way he has obtained remarkable results, and if not able to declare with M. Glénard, that in his hands no deaths occur from typhoid, he is happy in being able to affirm that deaths occur but rarely.

SUCCESSFUL EXTIRPATION OF THE SPLEEN.—Dr. FERNANDO FRANZOLINI, attached to the Civil Hospital of Udine, and well known in Italy as a bold and careful operator in cases of abdominal surgery, has the honor of being the first in his own country to remove with success a diseased spleen. The operation has been performed now some 25 times in Europe, of which 3 or 4 cases were in Italy, with the result of saving in all 6 patients. Dr. Franzolini operated in the hospital named, on September 20, ult., upon a young woman of 22 years of age, affected with "simple, true, idiopathic hypertrophy" of the organ, and a month later she was reported as having recovered. The tumor extracted was 9½ inches long by 6¼ inches wide, and weighed over 3 pounds. The abdominal incision extended from 4¾ inches above the umbilicus to 4 inches below it, and the operation lasted 1 hour and 25 minutes. The method of Lister was fully carried out. All of the ligatures were dropped into the abdominal cavity, and the wound was closed without drainage. No blood escaped into the abdomen.

Dr. Franzolini was also the first in Italy to perform Battey's operation with success. This was on August 14, 1876, and to remove, with like result, the uterus and ovaries in a non-pregnant woman. His only Porro case was lost, as the woman was *in extremis* when he operated upon her.

LEUCOCYTHÆMIA.—Dr. J. E. GRAHAM, Lecturer on Clinical Medicine in Toronto School of Medicine, gives the following as his conclusions from the study of a case of leucocythæmia:

1. That the essential features of leucocythæmia are the lymphoid growths, and the leucocytes found in the blood derived from them. 2. That the existence of similar growths is the essential feature of Hodgkin's disease, but in it the cells, for some reason which I cannot explain, do not find the way into the circulation. 3. That in both diseases the presence of these growths or deposits interferes with the manufacture of the red corpuscles producing anæmia. 4. That these growths bear a strong resemblance to those of a malignant character, especially sarcomata. 5. That progressive pernicious anæmia may arise as a consequence of leucocythæmia or Hodgkin's disease in the same way as it sometimes results from pregnancy, or any other condition which interferes with the proper elaboration of the blood.—*Canadian Journal of Medical Science*, November, 1881.

REMOVAL OF UTERINE POLYPI.—At a recent session of the Paris Academy of Medicine, the procedure adopted by several surgeons for the removal of uterine polypi was brought out in the course of the discussion. Léon Labbé uses the galvano-cautery; Verneuil, the wire écraseur; Gosselin, scissors; and Trélat contends that each plan has its excellences, and may be employed according to circumsantces.

DIABETES INSIPIDUS TREATED BY ELECTRICITY.—Mr. C. P. B. CLUBBE reports the case of a woman, aged thirty-five, who was suffering from diuresis, and in whom iron, nux vomica, valerian, and bromide of potassium had been used without any marked effect. Faradism over the region of the kidneys was then employed every day for about twenty minutes for twenty weeks. There was very decided improvement up to the seventh week, when the daily average of fluid passed varied very slightly; improvement, however, being constant. Treatment was then stopped, and six months afterwards she was no worse, though still passing from six to seven pints of urine daily.—*Lancet*, October 29, 1881.

PROF. TOMMASI-CRUDELI ON THE MALARIA OF ROME.—In 1879 KLEBS and TOMMASI described the malaria microbe—*bacillus malariæ*. The history of this parasite is not complete from the point of view of its pathogenetic and morphologic properties, but enough is known of its biological status to throw great light, it is probable, on certain important questions of public hygiene.

The bacillus malariæ is an organism requiring air. The germs or sporules are often encountered in soils of very different composition, and frequently poor inorganic substances. Malarial soils are often found in localities which are not, and have never been marshy. In Italy malaria-breeding soils are found in some lowlands and on some mountains. On the other hand, all marshes are not malaria-producing. In all malarial localities the multiplication of the bacillus malariæ takes place under three conditions: a temperature of about 68° F.; moderate but permanent humidity; and the direct action of the oxygen of the air on all parts of the mass. If one of these three conditions is absent, the multiplication of the bacillus and the development of the sporules are arrested. Hence it is that the most pestilential marshes do not engender malaria—although the temperature may be very high—when they are wholly covered with water, and no air can penetrate to the malaria-breeding soil. In the mud of malaria marshes the malaric ferment is always associated with a septic ferment. This association may be considered fortuitous. It is easy, in fact, to terminate all the phenomena of putrefaction in the palustral mud, and also to remove from them the power to produce septic infection, by means of a proceeding which augments the production of the malarial ferment to that degree that it becomes capable of producing pernicious fevers.—*Journal de Thérapeutique*, October 25, 1881.

PURPURA HÆMORRHAGICA IN ITS RELATIONS TO MENSTRUATION AND PREGNANCY.—Dr. ALBERT PUECH gives the following conclusions as expressing the results of his study of purpura:

1. Purpura hæmorrhagica occurs more frequently in the female than in the male.

2. It exerts a marked influence on the uterus whether in the empty or gravid state.

3. In the empty state, its influence can be manifested in three ways: *a*. It can suppress the menstrual discharge, and substitute it vicariously by its periodic occurrence. *b*. It may simply exaggerate the menstrual flow (*menorrhagia*). *c*. It may itself cause a hæmorrhage from the uterus (*metrorrhagia*).

4. During pregnancy, purpura has a tendency to cause abortion or premature labor.

5. Prognosis should in all cases be guarded, but in a general way it may be said that purpura is more serious in the woman than in man, and in pregnancy than when the uterus is empty.

6. Metrorrhagias have a graver prognosis than menorrhagias.—*Annale de Gynécologie*, October, 1881.

A CASE OF MANIA AFTER SCARLATINA.—Cases of psychical disturbance as a consequence of scarlatina are extremely rare, two cases, as far as we know, being all that have been as yet reported. The case reported by Dr. J. ROBUSKE, in which a cure was ultimately affected, is therefore deserving of mention. The patient, a man aged twenty-one years, after a mild attack of scarlatina, in which there was delirium, was affected with hallucinations and subjective sensations; he could not be kept in bed, moving restlessly up and down his room, and tearing his clothes and bed coverings. This condition lasted about a week, when, under the action of chloral and morphia, he gradually improved; was willing to remain in bed and take nourishment. A decided desquamation of cuticle occurred at about this time, accompanied by violent neuralgia of the lower extremities; after about two weeks illness in all, he recovered completely.—*Deutsche Med. Woch.*, Oct. 8, 1881.

CALABAR BEAN IN TETANUS.—Mr. J. THOMPSON HAYNE reports three cases of traumatic tetanus treated with hypodermic injections of one-sixth of a grain of extract of physostigma; of his cases two recovered and one died.—*British Med. Journ.*, Oct. 29, 1881.

A NEW SYMPTOM OF DISTURBANCE OF THE BILIARY FUNCTION.—From a long and valuable article on this subject, MM. LÉPINE and GUÉRIN draw the following conclusions: 1. It is possible in an animal, either by establishing a biliary fistula in the peritoneal cavity, or by keeping the biliary passages for several hours under pressure, to produce the passage into the urine of an extraordinary quantity of incompletely oxidized sulphur, additional proof of its biliary origin being found in the slightly oxidizable properties of taurine and its derivatives.

2. In man, above all, when the excretion of bile is obstructed, the same anomaly may be found in the urine, though in a less degree. In general, it is transient, so that in a few days the opposite extreme may occur, or the normal condition be regained. In every case, the essential characteristic of this condition is not the increase alone of incompletely oxidized sulphur, but the increase in the *proportion* of difficultly oxidizable sulphur.—*Révue de Medicine*, Nov. 10, 1881.

COLLYRIUM FOR DISSOLVING METALLIC FOREIGN BODIES FROM THE CORNEA.—Dr. RODRIGUEZ reports the following case (*Revista de Scienctas Medicas*, 25 Oct., 1881).—A blacksmith, aged eighteen years, while forging a piece of iron, received in his left eye a small splinter of the metal, which remained there incrusted, in spite of all attempts to remove it. The following wash was then employed: Rose water, 90 grm.; Iodine, .05 grm.; Iodide of Potass., .05 grm; the result was extremely satisfactory. The particle of metal was transformed into a soluble iodide of iron, and all traces of the foreign body had disappeared. The cornea regained its normal condition, and vision remained unaffected. —*Journ. de Méd. de Paris*, Nov. 12, 1881.

THE TREATMENT OF SOFT CHANCRES AND CHANCROUS BUBOES BY SALICYLIC ACID.—Without being an infallible specific which will take the place of all the other agents employed in these cases, salicylic acid is capable of rendering the most important service. It has the merit that it is without odor, gives but little pain, is soluble in alcohol and glycerin, and does not soil the linen. As a vehicle, glycerin presents many advantages: it does not evaporate, and it maintains on the surface of the ulcers a permanent coating which prevents the access of air. The following formula is employed by Dr. Autier: Acid Salicylic, 2 grammes. Glycerin, 100 grammes.—*Thèsé de Paris—Dr. Autier*, *Journal de Thérapeutique*, October 25, 1881.

SUCCESSFUL PORRO OPERATION.—The seventh Porro operation at the Santa Caterina Hospital of Milan, and the fifth success in order, was performed by Dr. Paolo Negri, Second Assistant of the Royal School of Obstetrics. The case was one of malacosteon, with a badly deformed pelvis; and the operation was performed on October 9th inst. Two weeks later the woman was regarded as safe for recovery. This gives Italy 34 Porro operations and 13 recoveries. The 7 cases in Santa Catérina Hospital resulted as follows:

	Deformed by	Operator.	Woman.	Child.
1.	Rickets.	Prof. Chiara.	Died.	Alive.
2.	"	" "	"	"
3.	Malacosteon.	" "	Recovered.	"
4.	Rickets.	" Mangiagalli.	"	"
5.	"	" Chiara.	"	"
6.	"	" Mangiagalli.	"	"
7.	Malacosteon.	" Negri.	"	"

A NEW SOLVENT FOR DIPHTHERITIC MEMBRANE.—Dr. W. HALE WHITE recommends spraying the throat, in cases of diphtheria or the trachea after tracheotomy, with an acid glycerin of pepsin, warmed up to 110° F. The fragments of membrane coughed up in the case in which it was used, he reports, were very soft and gelatinous as compared with ordinary diphtheritic membranes. He thinks, however, that the chief value of the pepsin is not to digest the large pieces of membrane, but to mix with the secretion in the smaller bronchi and prevent the formation of membrane there. The child died some time after, how long is not stated, from broncho-pneumonia; and it is reported that there was no evidence to show that the pepsin had had any evil effect on the air-tubes.—*Lancet*, October 22, 1881.

POISONING WITH CHLORATE OF POTASSIUM.—From a number of experiments made by Messrs. BROUARDEL and SHOTE they conclude that: *First.* Numerous examples leave no doubt as to the fact that large doses of chlorate of potassium (35–40 grammes for an adult, eight or ten times less for a child of two or three years) can produce death. *Second.* The intervals during which the successive doses are administered exert a great influence on the development and gravity of the toxic effects. If the doses are separated by long intervals, rapidity of elimination diminishes the danger. When they rapidly succeed one another, the danger is much greater.—*Jour. de Méd. de Paris*, October 1, 1881.

TREATMENT OF SPERMATORRHŒA.—Dr. NOWATSCHEK reports in *Schmidt's Jahrbücker*, January, 1881, a case of spermatorrhœa consequent on typhoid fever, the diagnosis resting on the presence of spermatozoa in the fluid which was constantly oozing from the urethra. Iron, quinia, and cold applications to the genitals were tried in succession with some success, but a cure was not accomplished. Lupulin, camphor, and bromide of potassium were without effect. Atropia was then employed, and the patient was completely cured in five days. The author cites a second case where he was equally successful with the hypodermic injection in the perineum of a one per-cent. solution of atropia.—*Jour. de Méd. de Paris*, October 8, 1881.

ARSENIC INTERNALLY AND SUBCUTANEOUSLY IN THE TREATMENT OF LYMPHOMA.—A woman of sixty-five had difficulty in swallowing, and breathing and suffered from general feebleness, deafness, etc. Her condition was cachectic. Examination revealed a tumor in the posterior pharynx filling up the nasal and pharyngeal cavities; the submaxillary and axillary glands were also swollen and hard. These growths were made to disappear, and the woman was regarded as cured in five months. This remarkable result was accomplished by the combined internal and parenchymatous administration of Fowler's solution. The arsenic was given in large doses, mixed with acetated tincture of iron, from 8 up to 25 drops three times a day. In this way 28 grammes were consumed in the course of the treatment. The injections consisted of equal parts of Fowler's solution and distilled water, of which there was injected from one to three-tenths of the capacity of a Pravaz syringe (about 3 to 9 minims). There was but little reaction of the general organism, but a marked acceleration of the pulse. Locally, the tumors increased considerably in size with the first injections, but after the second week rapidly declined.—*Berl. Klin. Wochen.* 1880, No. 52.

CZERNY has employed the method of Billroth, above described, in the cure of glandular lymphomata. In six months he obtained a complete cure of a case, in which the patient had taken 746 drops and had received 76 injections of 10 drops each.—*Wien med. Wochen.* 1881, No. 2.

TREATMENT OF SUBACUTE AND CHRONIC ARTICULAR AFFECTIONS BY OAKUM.—Dr. CONSTANTIN PAUL has employed with success, at Lariboisière, the substance called *oakum*. The affected articulation is completely enveloped to a thickness of 1 or 2 centimetres. Treated thus, a case of *arthritis deformans* has been much relieved in some weeks. It has produced the best effects in *bronchitis*, in place of Burgundy Pitch plaster.—*Bulletin Gén. de Thérapeutique*, Sept. 15, 1881.

THE METHODICAL EXERCISE OF RESPIRATION IN RELATION TO THE CONFORMATION OF THE CHEST AND TO THE GENERAL HEALTH, is the title of a paper by Dr. DALLY, in which, after discussing various physiological questions concerning the respiratory organs, he proposes certain methodical movements for exercising the thorax.

1. The first or normal, is the vertical position, perfectly erect, as if standing against a wall, the arms hanging by the side. This position should be taken and kept for ten minutes at a time, a number of times a day.

2. The two arms and the hands are extended horizontally forwards, the palms of the hands facing. The hands are separated slowly, whilst the chest is inclined forward. Remain in this position thirty seconds, and inspire deeply by the nose. Return to the initial position, and expire. Execute this movement six times.

3. The arms hang by the body; raise them upwards —the fingers well extended—above the head, the palms looking forward. Take a deep inspiration. Let fall the arms alongside the body, palms open, and expire slowly.

4. Double rotation at the side. The subject being in the normal position (first), executes as large as possible, the arms well extended, double rotation laterally, and inclining the trunk forward each time that the arms are thrown behind, and never projecting the belly forward. This movement is executed entirely by the scapulo-humeral articulation.

5. The arms are crossed horizontally, the palms of the hands looking backward. Flexion lateral, alternately, of the trunk. The flexion will be then regular, transverse, the abdomen drawn in, the legs extended apart, the pelvis fixed. The limit of the flexion is the vertical position of the elevated arm. Mild inspiration during the flexion; at its termination expiration. Execute these movements from six to eight times.

These exercises, if faithfully carried out, improve the shape and capacity of the thorax and check the development of incipient phthisis. According to Dr. Dally, dyspnœa, polysarca, and arthritic conditions are removed or sensibly ameliorated. Venous stases, varicose dilatations, and infarctions are, after some weeks of such movements, much improved when the circumstances are favorable. The great obstacles to this hygienic medication in our civilization are, the habitual idleness and laziness, and the indisposition to devote time and *interest* to such means, is the conclusion of Dr. Dally.—*Bull. Gén. de Thérap.*, Sept. 30, 1881.

INJECTIONS OF BROMIDE OF POTASSIUM IN GONORRHŒA.—In eighteen patients under observation there was noted in fifteen a rapid diminution or complete suppression of the erections. The injections are not very painful. They are used five times a day, the last injection being practised just before retiring. They should be retained in the canal one or two minutes.

The following is the formula: Water, 150 grammes. Glycerin, 10 grammes. Bromide of Potassium, 6 grammes. Laudanum, 2 grammes.—*Journal de Thérapeutique*, October, 1881.

CASE OF GALVANO-PUNCTURE IN AORTIC ANEURISM.—Mr. RICHARD CANNON reports the case of an aortic aneurism which had almost reached the point of rupture, the skin being reddened and very thin over the tumor, which was cured by the insertion of two needles connected with twelve Stöhrer cells. It is stated that when the needles were withdrawn no current was to be detected, so the favorable results may with equal probability be attributed to the mere presence of the needles or to the electrolytic action. The needles remained in the tumor only twenty minutes; at the end of ten days the tumor, which had only been the size of a walnut, had flattened down to the chest walls, pulsation and redness had disappeared, and there was no pain or cough. Iodide of potassium was administered internally throughout the treatment—*Lancet*, October 22, 1881.

GENITAL REFLEX.—Dr. E. W. Saunders reports, in the *Alienist and Neurologist* for October, 1881, four cases of paroxysms of abdominal pain associated with adherent prepuce. In each case a cure followed circumcision.

SENILE OSTEOMALACIA.—From a long paper on this subject Dr. EMILE DEMARGE draws the following conclusions:

1. Osteomalacia can develop in old people as in adults.

2. We can admit clinically the existence of a form of osteomalacia localized in the vertebral column, the thorax, and the pelvis, and, although this form is more frequent in the aged, it can also develop in adults.

3. So-called senile osteomalacia is completely distinct from senile osteoporosis, and has the same lesions as true osteomalacia occurring in adults, from which it differs simply in the age of the subject in which it develops.—*Revue de Medicine*, September 10, 1881.

HÆMOSTATIC PILLS.—Dr. Huchan prescribes the following formula for hemorrhages of different kinds, as metrorrhagia, epistaxis, hæmoptysis, etc.

℞ Ergotin, Quiniæ Sulph. āā ʒss Digitalis, Ext. Hyoscyami āā gr. v. M. ft. pil. no. x. One every 2, 3 or 4 hours.—*Journal de Thérapeutique*, 10 November, 1881.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances for the NEWS may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JANUARY 7, 1882.

VOLUME FORTY.

IN entering upon the fortieth year of its publication, and prompted by the desire of more fully meeting the requirements of the medical literature of to-day, and of furnishing the profession with a medium of more frequent intercommunication, *The Medical News* begins its weekly issue under most encouraging circumstances, and with the cordial commendation of a very large number of the foremost and ablest workers in the profession in all parts of the country, who have also assured its high standard of excellence by specifically promising to enrich its pages by their contributions.

The plan of the weekly *News* is so fully and faithfully set forth in the Publisher's prospectus, and in this first number, that it seems unnecessary to dwell further upon it, beyond saying that we shall especially endeavor to cultivate the vast field of clinical observation, embracing the scope of all the specialties, and to stimulate the publication in our pages, for the benefit of the whole profession, of the rich stores of clinical experience, the lessons of which heretofore have been for the most part confined to single observers. At the same time we shall assiduously labor to render every department of the *News* worthy of the entire profession which it aims to represent.

The functions of a weekly medical journal are multifarious: it must be the medium of transmitting the earliest intelligence of medical discoveries and progress; it must, in its editorial columns, represent the living thought of the day, and, while holding positive views, fully, fairly and forcibly discuss all current topics which interest the profession scientifically, socially, or politically; it must present a faithful record of the progress of medical science in all countries; it must give prompt and reliable information concerning all matters, wherever they may be, which are of general medical interest; it must, in fine, fulfil the rôle of a professional newspaper. To enable it to attain this aim, the *News* will have the advantage of a large, carefully selected, and experienced editorial staff, of a corps of collaborators, embracing the most prominent workers in the medical profession of this continent, of special correspondents in all the principal cities of the world, and of a large reportorial staff, which will furnish full and accurate reports of the meetings of the principal medical societies in the United States and Canada which are available. With the ample resources and abundant experience of the publishers the profession are too well acquainted to render necessary any assurances as to the manner in which their portion of the work will be performed.

The columns of the *News* are open to the whole profession. Communications to every department are invited, and liberal compensation will be made for all original articles when published.

In developing so comprehensive a plan, which in its accomplishment will make a periodical that shall be absolutely indispensable to every physician who would keep himself abreast the professional thought and action of the day, and in its execution will require unremitting labor and involve weighty responsibility and a very large pecuniary expenditure, the *News* is encouraged by the belief that the profession want only the best, and that a periodical conducted on so broad and liberal a basis as is proposed will receive their unqualified and generous support, without which such enterprise becomes impossible.

In its management, the *News* will always be conducted for the advancement of the interests of the whole profession, and it shall be absolutely uninfluenced by any personal, school, or local interest; modelled on the highest type of weekly medical journalism, its scope shall be cosmopolitan and its character national.

With such a plan, and in the hope of its meriting their approbation and support, the first number of the weekly issue of *The Medical News* is presented to the profession.

LOCAL TREATMENT OF LUNG CAVITIES.

IN the number of the *American Journal of the Medical Sciences* for October, 1881, we find a notable paper by Drs. Fenger and Hollister, of Chicago, on the "Opening and Drainage of Cavities in the Lungs." Our attention is thus invited to an extremely interesting, if not altogether new, practice. During the present century there have been numerous attempts to reach, by more direct means, the cavities excavated by tuberculous ulcerations, not to

speak of pleural effusions. The subject has been revived anew, and a more practical direction given to the operative procedures, by Professor Mosler, of Greifswald. On the 23d of September, 1873, Professor Mosler read a paper before the Society of Naturalists and Physicians, assembled at Wiesbaden, which subsequently appeared in the *Berliner Klinische Wochenschrift* for October 27, 1873, under the title—*Ueber lokale Behandlung von Lungenkavernen.* Mosler's scheme included the opening and drainage of pulmonary cavities by suitable drainage-tubes, and the application to the walls of the cavities of appropriate topical agents.

Prof. William Pepper, of Philadelphia, was engaged in a similar plan of treating lung cavities, at or about the same time, his preliminary publication appearing in *The Philadelphia Medical Times* for March 14, 1874.[1] Pepper's paper was "On the Local Treatment of Pulmonary Cavities by Injections through the Chest Wall."

Very recently drainage of the pericardium has been successfully carried on by Rosenstein, of Leyden. It is true, paracentesis of the pericardium has been frequently performed, and but a few months ago a very meritorious treatise on this topic appeared from the pen of Dr. J. B. Roberts, of Philadelphia. Rosenstein's case of drainage is, however, novel; for although puncture of the sac and fistulous openings externally are comparatively common, no one has before this deliberately opened the pericardium and inserted drainage-tubes to secure prompt removal of purulent fluid. The success of this case justifies the belief that the principles of treatment now established for empyema are equally applicable to the suppurating pericardium. It has been clearly established that in empyema, the main point is to secure a ready and complete evacuation of the pus; if necessary, exsecting a rib for that purpose. Can the same methods be applied to suppurating cavities of the lungs? To render the local conditions the same, it is necessary that the cavity be single, and that complete adhesions with the walls of the thorax exist. Let us see how far this declaration is sustained by the facts before us.

Of the six cases (five from various sources, and one their own) narrated by Drs. Fenger and Hollister, five proved fatal and one was cured. The fatal cases were examples of pulmonary disease, either inflammatory or tubercular; the successful case was one of echinococcus of the lungs. Davaine (*Traité des Entozoaires*, etc., Deux, Éd., Paris, 1877,) reports two cases of echinococcus of the lungs, in which operative procedures were successful. So long ago as January, 1812, Fréteau opened a cavity (*Opération de l'empyeme*) and discharged 500 hydatids, the rest being expectorated. In 1855, Dr. Vigla made an exploratory puncture with a trocar, in a suspected case of this kind, and injected into the hydatid cavity about 8 ounces (250 grammes) of a compound solution of iodine. (*Arch. Gen. de Médecine*, 5e Serie, tome vi., p. 282.) This case proved entirely successful.

Can the results of experience in the treatment of echinococcus cysts of the lungs be applied to phthisical cavities? We think not, and for the following reasons:

An echinococcus cyst is a purely local lesion, and the tissue of the lungs beyond the seat of deposit is healthy. The presence of an echinococcus cyst in the lungs does not involve any necessary change in the structure or function of the other organs of the body. When entirely and successfully removed, the local disturbance caused by their presence subsides, and the *status in quo* is restored.

In the case of pulmonary cavities caused by the usual conditions producing them, it is extremely rare to find a single cavity without adjacent lesions. Besides the more or less extensive pulmonary disease, complications exist in various organs which exercise a marked influence over the fortunes of the case. It is certainly true that when a cavity exists suitable for the treatment by drainage, more or less extensive caseous and tubercular deposits, dilated bronchi, interstitial pneumonia, etc., coexist. The successful drainage of a cavity, under such circumstances, can effect but a temporary alleviation of the symptoms.

Before the drainage of a cavity can be attempted, the exact position of it must be ascertained. It may be affirmed in the most positive manner that no considerable depth of healthy pulmonary tissue can be with propriety penetrated. There must be complete adhesion between the pulmonary and costal pleura at the site of the cavity. The cases conforming to these requirements are examples of advanced disease in which extensive excavations have formed in the upper or middle lobe, the anterior boundary being composed of the pleura, much thickened by organized exudations. It is difficult to conceive of any advantage to be derived from drainage of such a cavity, if, as is usual, extensive lesions coexist, and if the cavity has free communication with a bronchus. On the other hand, if the cavity occupy the major part of the diseased area, and is not satisfactorily drained, the general condition being fairly good, certainly results may be achieved by drainage sufficient to justify the procedure.

The questions concerned in dealing with hydatid cavities in the lungs are, as has been stated, very different. Without entering too much into detail, it will suffice to say that there are two modes of dealing with them, determined by the local conditions.

[1] Dr. Pepper's detailed publication appeared in the *American Journal of the Medical Sciences* for October, 1874.

When there is a solitary echinococcus cyst, which has merely displaced the pulmonary tissue without exciting a limiting inflammation, as in the case of Dr. Vigla, before mentioned, it suffices to inject some iodine solution, which causes the death of the parasite, after which it undergoes a fatty metamorphosis and disappears. If, on the other hand, the conditions are as in the case of Drs. Fenger and Hollister, and in the case of Dr. Fréteau—that is, a limiting inflammation, suppuration, and vast numbers of daughter and granddaughter vesicles — the proper practice consists in the evacuation of the cavity, in thorough drainage, and washing out with carbolized water, etc.

The injection of pulmonary cavities is a more generally available expedient. Although no distinctly curative results have been thus far obtained, there is promise in the method. The remedy thus employed has been iodine in some form. It is not essential to the success of this expedient that the cavity injected be situated superficially, or fixed by adhesions to the thoracic wall. If the diagnosis be accurate, the cavity can be readily reached by a suitable needle, even although somewhat deeply placed. This method may, in the future, be utilized for a different purpose. It may be possible to remove extensive caseous or tubercular deposits, by injecting into them medicaments which will exert a solvent action on the morbid materials, leaving the proper anatomical elements unharmed.

DRAINAGE OF THE WHITE HOUSE.

AN examination of the sanitary condition of the Executive Mansion at Washington, with especial reference to the plumbing and drainage, was made necessary by the repeated complaints of its insalubrity, to which unusual prominence has been given by events occurring within the past few months. This investigation has been made by Mr. George E. Waring, Jr., who transmitted to Col. Rockwell, in charge of public buildings and grounds, a preliminary report containing the results of his observations. It is gratifying to learn that the defects were less serious than general rumor would lead us to expect. He found the quality of the plumbing reasonably good, but the system of drainage antiquated and defective, and in part radically wrong. This is what might have been expected from alterations and additions made from time to time by different persons, in lieu of a radical reconstruction in accordance with our present knowledge of the necessary sanitary requirements.

Among the defects discovered may be mentioned, the want of proper ventilation of the soil-pipes, in one or more cases its entire absence; an arrangement of the tank for supplying a considerable portion of the house with water in such a manner as to render it subject to contamination from the main soil-pipe and from other sources; want of ventilation of two of the water-closet compartments, and the use, in one case, of the pan closet, which is now generally condemned as one of the worst of that class of sanitary appliances.

The authorities have doubtless been familiar with these faults, and their recommendations, if reported upon, have shared the fate which is inevitable when the necessary funds to defray the expense of reconstruction are withheld. It is humiliating that a great national calamity should be required as the occasion of which advantage must needs be taken to compel a thorough overhauling of the drainage arrangements of the White House, which should not, under any circumstances, have been permitted to remain in so unsatisfactory and neglected a condition. We are informed that the temporary modifications suggested by the report have been carried into effect, and that safety is now ensured.

When Col. Waring makes his final report, it is to be hoped that the recommendations for reconstructing the sanitary arrangements of the Executive Mansion in accordance with the requirements of the best practice of sanitary science will at once receive proper consideration, and that Congress will promptly make the necessary appropriation, so that in the future we shall hear no more about the insalubrity of the White House, from this cause, at least.

ONE SYMPTOM TREATMENT OF LOCOMOTOR ATAXIA.

THE hygienic treatment of the ataxia of posterior spinal sclerosis, oscillates between absolute rest and active exercise. Now comes Dr. Mortimer Granville with an expedient, which is opposed to the "rest cure," and which he says in less than three months, if his results are trustworthy, not only will the symptom which was regarded as conclusively indicating the existence of an incurable disease, be eliminated from the case, but other symptoms will disappear with it, and the general state of the patient be sensibly improved. We give the plan in his own words (*The Practitioner*, November, 1881, p. 336.)

"The patient is directed to stand with his eyes closed in his bath, after pouring a small can of cold water down the spine, and to persevere in the attempt to do this *steadily* for, at first a quarter of an hour, and as his state improves, for half an hour every morning. He is to be furnished with a chair or rail at hand, to which he can cling in case of need; but instructed to avoid using it except in actual danger of falling. When he commences the daily exercise, he will probably for some two or three weeks make little progress, but after this he will begin to be able to stand," etc.

Dr. Granville recommends in sthenic cases the

application of a mustard plaster at night, the full length of the spine, until redness is produced, in addition to the cold douche in the morning.

"FREE TRADE IN MEDICINE."

OUR valued contemporary, *The Medical Times and Gazette* of London, in a recent issue (November 12, 1881), discusses the subject of "Medical Education and Registration in America." In this article the regulations in the various States are commented on with fairness and candor. We refer to it, however, not to discuss the subject of medical education, *per se*, but whether this were better left to the medical profession and its legitimate institutions, or be made the subject of political and civic regulation. As our contemporary states it, "the conditions under which men should be allowed to practise medicine, the amount and kind of knowledge which they should be obliged to show, the way in which their possession of that knowledge can best be tested, the length of the preliminary training which they ought to be required to undergo, the extent to which the details of that training should be regulated by compulsory rules or left to individual option, these are questions upon which there are wide differences of opinion in this country."

In England and on the Continent of Europe, the system of "compulsory rules," of entire governmental control, obtains; in this country, there is, as our contemporary well expresses it, "free trade in medicine," and "the provision of competent medical advisers is left, so far as the central authority is concerned, to the unhampered operation of the law of supply and demand." Which is the better system? In England, it appears, there are wide differences of opinion on this question. They are not altogether satisfied that their plan is the better one. There is a large and influential minority who hold that the American system, notwithstanding the abuses to which it is subject, is, on the whole, the better. They observe that the profession of medicine, left to its own resources, and untrammelled by obstructive egislation, is remarkably successful in the development of its powers. In the same article from which we have quoted, we learn that "American medical literature is very voluminous, and characterized by great originality, inventive genius, industry, and practicality." Now, as all the world knows, our medical literature is the growth of this century, of, indeed, the last thirty or forty years, and it is already being reproduced in European languages. It is also well known that certain departments of our art have been created in this country, and others notably improved. Free trade in medicine seems to work well here. Ought we not continue, as heretofore, to permit the law of supply and demand to regulate our growth? We may properly correct flagrant irregularities by appropriate legislation, but ought we not refrain from such interference in our organizations and methods by authority of the government, as would hinder that free development and successful progress which we owe to our system of free trade in medicine?

THE THORACIC DUCT IN THE PRESIDENT'S CASE.

IN another column we print an excellent letter from Mr. H. A. Kelly, a medical student at the University of Pennsylvania, who, with praiseworthy zeal, has carefully dissected the thoracic duct, with a view to determining whether it could have been injured, as has been inferred, in the case of the late President Garfield. His conclusion is adverse to any such opinion. It may interest our readers to know that the ball (calibre 44) is $\frac{7}{16}$ of an inch in diameter, and that the track of the ball (supposing it to be no wider than the ball itself) passed in the middle line, within about $\frac{4}{16}$ to $\frac{5}{16}$ of an inch of the anterior surface of the wounded vertebra. Posteriorly between the track and the spinal canal a slightly greater thickness of bone intervened.

Whether the thoracic duct was injured primarily, may be doubtful. But the drawings of the specimen show that the body of the vertebra was almost wholly eroded at several points anteriorly as well as posteriorly; and it is not at all unlikely that the duct may have become involved in the later inflammatory action, and have disturbed the processes of nutrition to such an extent as to account for the subsequent rapid emaciation.

It is remarkable that the aorta escaped injury, for the ball must have almost grazed it; and it is no less remarkable that the spinal cord was not involved by the secondary erosion; and that in lifting the President so frequently the weakened spine did not give way and produce pressure on the cord.

Our correspondent has done good service in his careful investigation of the facts anatomically.

THE NATIONAL BOARD OF HEALTH.

THIS Board has just issued its annual report. We venture to say that in scarcely any of the many reports presented to Congress will there be found more important matters compressed into briefer space than in this one of three and a half quarto pages.

We have only space at this time to call attention to the excellent and valuable special scientific investigations which the Board has directed to be made by eminent scientists in various departments, such as Wood, Sternberg, Remsen, Martin, Hering, Pumpelly, Mallet, Bowditch, Stephen Smith, G. A. Smyth, and others. The subjects are national in importance, and include diphtheria, malaria, air and water currents in soils, potable water, the sanitary condition of summer resorts, arsenical papers, etc.

We hope to allude hereafter in detail to the results already obtained.

The expenditures of the Board have been—mirabile dictu—far less than the appropriation. The special sum of $100,000, set apart for use in case of an epidemic, has fortunately not been needed.

REVIEWS.

THE STUDENT'S MANUAL OF VENEREAL DISEASES. By F. R. STURGIS, M. D. 12mo, pp. 196. New York: G. P. Putnam's Sons, 1880.

This little book is a condensation of much practical information concerning the venereal diseases, arranged in the form of lectures. Beginning with the simple venereal ulcer, the author describes in accurate terms the clinical history, the customary treatment, and the sequelæ of chancroid, syphilis, and gonorrhœa, formulating and emphasizing in italicized paragraphs the general truths which underlie the received methods of diagnosis and treatment of these maladies.

We cannot better give an idea of its general plan and scope than by quoting a few of these paragraphs:

"The initial lesion of syphilis is usually indurated; when present, this is of great value; but its absence, which sometimes happens, does not change the nature of the lesion; it still remains syphilis. When the induration is absent, the diagnosis has to be made from other characteristics."

"Syphilis always begins by an initial lesion, seated at the point where the virus gained entrance, never in any other way."

"Paralysis of single muscles, or sets of muscles, are (*sic*) nine times in ten syphilitic."

"The average case of syphilis runs its course in from eighteen to twenty-four months. Under proper and careful treatment the graver forms of the disease seldom occur. After the disease has apparently run its course, and anti-syphilitic treatment has been suspended, the patients should be kept under occasional observation for another eighteen months, and if in that time no symptoms make their appearance, they may make their minds easy about the future."

Nothing could be better adapted to fix fundamental principles in the mind of the student than these and many similar axioms which might be cited if space permitted.

Teaching intended for students must necessarily be dogmatic, and it cannot be expected that in a "manual" the author should give prominence to or should even mention theories opposed to those he himself holds. He should, however, for obvious reasons, endeavor to avoid disputed questions, and to state in the clearest and most unequivocal language those propositions which have received universal acceptance.

This has, as a rule, been well done. Paragraphs similar to those above quoted, and embodying in a concise and intelligible form, much information, familiar of course to specialists, but not so well known or understood by the general practitioner or by the student, are frequent throughout the book, and are generally admirable in their terseness and comprehensiveness.

When, however, he says that "urethritis in the female is always due to some venereal affection," p. 154; doubts the existence of "vesicular and bullous [*sic*] syphilides," p. 60; asserts without qualification that "a chancroid becomes *worse* under a mercurial course, which is poison to it," p. 59; that when complicated with phimosis, "the initial lesion does not ulcerate," p. 38; and that strapping of the testicle in epididymitis "has sometimes led to atrophy of the testis, and has been pretty nearly abandoned," p. 183, he lays himself open to criticism from those who upon any or all of these points venture to disagree with him.

There is a granular urethritis of females often following parturition, and becoming chronic, a traumatic urethritis, due to local irritation, sometimes, for example, to a vulvitis caused by rude and excessive copulation, and a urethritis which may appear consecutively to affections of the bladder, in any of which a suspicion, much more a dogmatic assertion, of the existence of venereal disease would be a great injustice to the patient.

The existence of vesicular and bullous eruptions as rare forms of syphilodermata, although also questioned by other syphilographers, has been, we believe, demonstrated beyond reasonable doubt; Dr. Sturgis does not distinctly say so, but of course refers only to acquired syphilis, as, a little later, in describing infantile syphilis, he remarks, p. 122: "The body is usually covered with large bullæ."

That a simple contagious venereal ulcer—a chancroid—is not commonly benefited by a mercurial course every one will allow, but that it necessarily becomes *worse* under it, or that there is any essential antagonism between the disease and the drug cannot be admitted. How seldom it becomes necessary to interrupt a mercurial course in the treatment of syphilis to permit of the cure of an intercurrent chancroid.

When phimosis comes on as a complication of the initial lesion, there is always more or less ulceration; indeed, it is in just these cases that the sore approximates most closely in its characters to the simple venereal ulcer.

In asserting that strapping the testicle has fallen into disuse, Dr. Sturgis undoubtedly represents the teachings of Cullerier, Bumstead, and others; but the cases in which atrophy has been attributed to it are, to say the least, open to doubt; no other bad results are even claimed to have been produced; and in this city the dressing is still very commonly employed. A procedure which, practised at the proper stage of this painful affection, will give rapid, safe, and certain relief, should not be discredited or discarded on such vague grounds. No other method of treatment except that by puncture—which is not adapted to exactly the same stage, is more repugnant to the patient, and has certainly been followed by herniæ testis—will compare with it in giving comfort and enabling the patient to resume his usual avocation.

We are pleased to see that he objects to the term "mixed sore;" but regret that, while discarding this title of that purely hypothetical lesion, he immediately alludes to it by a still more objectionable name, as a "double sore," and proceeds to speak of the simultaneous inoculation of two poisons, and their subsequent course and development—a view not by any means generally accepted even by dualists, and in many respects opposed to sound pathology.

Dr. Sturgis's assertion, already quoted, that in infecting chancre the induration is sometimes absent, might have been construed into an admission that syphilis sometimes follows the sore known as a "chancroid" or "soft chancre;" but he forestalls this by substituting for the latter the term "simple venereal ulcer," which he contrasts with the "specific venereal ulcer" or initial lesion. Now if by this Dr. Sturgis means that there are two venereal ulcers, one which is specific and one which is not, we heartily agree with him; but, as he subsequently proceeds to speak of "two poisons," of "two kinds of virus," of "double infection," etc., we perceive that in dividing these sores into "simple" and "specific," he has unintentionally misrepresented himself, as, according to these views, the simple sore is just as truly specific as the specific sore. We are the more

surprised at this, as Dr. Sturgis, not very long ago, was at least a skeptic as regards the specificity of the chancroid, if not a pronounced unbeliever.

In turning over the leaves at random, we find a number of examples of loose construction and ungrammatical or undignified expression, which might readily have been remedied by a careful revision.

Such points are, however, only alluded to because so good a book should not be marred by errors which would seem to indicate haste or carelessness in preparation. On the whole, we can cordially recommend it as a reliable and satisfactory guide in the diagnosis and treatment of venereal disease, and as containing much useful information, not found—or, what is nearly as bad, very difficult to find—in many more elaborate and pretentious volumes.

A SYSTEM OF SURGERY. Edited by T. HOLMES, M. A. *First American from Second English Edition, thoroughly revised and much enlarged*, by JNO. H. PACKARD, M. D., assisted by a large corps of the most eminent American Surgeons. Three volumes. Vol. I., 8vo, pp. 1007, Pl. ix and 245 wood-cuts. Philadelphia: H. C. Lea's Son & Co., 1881.

To edit Holmes' "System of Surgery" is no light work, and we must congratulate Dr. Packard on the manner in which it has been done. The authors of the original English edition are men of the first rank in England, and Dr. Packard has been fortunate in securing as his American coadjutors such men as Bartholow, Hyde, Hunt, Conner, Stimson, Morton, Hodgen, Jewell and their colleagues. They have revised and added to all the articles except three, which were found so complete as not to require any additions. The new matter varies considerably in amount and character, but is always judicious and useful. In some cases it is very slight, while in others the additions are large in amount and radical in character. Perhaps no chapter has been more difficult to revise than the one on Tumors and Cancers, by Sir James Paget and C. H. Moore. The nomenclature and classification of such new growths has undergone such a decided change within the last few years, that Dr. Longstreth has had no little trouble in welding the old and the new matter into one homogeneous whole. It has been well done, however, and presents the matter intelligibly, and as briefly as possible. To our thinking, it would almost have been better to have written the chapter entirely anew, as is to be done with the articles on the Skin, and Absorbent System. But in view of the still unsettled state of our knowledge, perhaps it is better as it is, since it makes the reader more familiar with the different methods of classification, and therefore the varying terms employed by different authors.

The illustrations of a technical book, especially one that is intended to be so widely circulated among practitioners in the country, where they can have access to no museums and rarely perhaps have post-mortem specimens to examine and study, are of the greatest importance. We are glad, therefore, to see that the original number of wood-cuts has been increased about fifty per cent., while the chromo-lithographs of the second English edition (for they did not appear in the first) have been very well reproduced, but their lettering is too faint, and at night especially is not readily legible.

As a whole, the work, if we may judge by this first volume, will be solid and substantial, and a valuable addition to the library of any medical man. It is more wieldy and more useful than the five volume English edition; and with its companion work—Reynolds' "System of Medicine,"—will well represent the present state of our science. One who is familiar with those two works will be fairly well furnished head-wise and hand-wise.

A TREATISE ON THE DISEASES OF THE NERVOUS SYSTEM. By JAMES ROSS, M. D., M.R.C.P., Lond.; Assist. Phys. to Manchester Royal Infirmary. 2 vols., pp. 594, 1000. New York: William Wood & Co., 1881.

These portly volumes are intended, in the words of the author's preface, to give a tolerably full account of the diseases to which the nervous system is liable, with the exception of the mental diseases. The first volume opens with a consideration of the structure and functions of the nervous system, in which the author treats of the anatomical arrangements and the physiological functions. This is well brought up to date. Thus he gives an account of Meynert's Projection System. He follows Landois' Physiology in his accounts of the anatomical structure, and his figures are derived from this source chiefly. As regards microscopic structure, he has based his account on Ranvier's largely. General etiology and general symptomatology close the first, or general part of the work.

In Chapter VI., he discusses trophoneuroses. In this we observe that he passes under review the contributions of Waller, Schiff, Erb, and especially of Ranvier. In the chapter on the diseases of the nerves of special sense, there is a good account of the ophthalmoscopic appearances in optic neuritis, and a plate exhibiting the changes in the fundus of the eye. This part of the work relating to diseases of the cranial nerves, is well illustrated by cuts taken from Landois' and Hermann's physiology.

Pursuing an anatomical arrangement, he discusses diseases of the cervical and brachial plexuses after the study of the cranial nerves. He first takes up the sensory, and follows with the motor affections. In the diagnosis of paralyses, he uses electricity in accordance with the most recent views, and gives a good account of the reactions of degeneration in the peripheral and spinal paralyses.

The second volume opens with the diseases of the spinal cord and medulla oblongata, or rather with an anatomical and physiological introduction. The "system diseases of the spinal cord and medulla oblongata"—the poliomyelopathies—are well handled, and the articles are illustrated with plates and wood-cuts. The contributions of the most recent publications are here fully presented. In "the mixed diseases of the spinal cord and medulla oblongata," we find the same careful and thorough treatment.

The last part is devoted to the diseases of the encephalon, in which the doctrines of the localization of functions are fully stated, and the various maladies adequately described.

From this brief sketch, it will be seen that this work presents in full detail the diseases of the nervous system. It is a highly creditable production. It is, however, too voluminous, and might be much condensed with advantage. The anatomical and physiological introductions to the several divisions of the subject, might have been omitted, because these topics are treated of more fully by those special works devoted to anatomy and physiology respectively. On the other hand, it may be alleged that the student of nervous diseases will nowhere else find all the facts brought together in a form so convenient and serviceable. Again, cases are related in detail occupying much space, and although interesting enough in themselves, are out of place in a strictly didactic treatise. With these exceptions, we have only praise for the work, which we regard as eminently suitable to the needs of students of nervous diseases. It is true we do not find any original contri-

butions to knowledge, but we have offered that which is better for the purposes subserved by such a work—a full and accurate account of the subject, showing the author's mastery of the whole domain of nervous maladies.

THE MOTHER'S GUIDE IN THE MANAGEMENT AND FEEDING OF INFANTS. By JOHN M. KEATING, M. D., Lecturer on the Diseases of Children at the University of Pennsylvania, etc. 12mo, pp. 118. Philadelphia: Henry C. Lea's Son & Co., 1881.

Though the average of births to marriages may be steadily decreasing, the number of "Mothers' Guides" and "Infant Managements" is decidedly on the increase, and in a time which may be calculated with some accuracy, there will be a special guide, neatly bound and convenient for the pocket, for each mother. But as by that time the number of medical graduates will allow of one for each family, he will probably recommend his own guide for his family, or furnish it at a reasonable rate.

Dr. Keating's Mother's Guide is of a higher order than usual, and draws dangerously near that line which should separate the popular from the true scientific medical work. Perhaps he even oversteps the line, but if so, he does it with rare judgment and discretion. It is just the book to give the mother about to take her family to the country or sea-shore, where doctors are scarce or difficult to reach. Guided by it, almost any woman of average intellect will be rendered better able to cope with the sudden emergencies of croup, cholera infantum, or convulsions, and yet, we trust, will still feel that the doctor, when he comes, knows a little more about the case than Dr. Keating's book has taught her; for on this point the author has been especially on his guard. While we do not agree with him in his estimate of the relative success of wet nursing and bottle-feeding, still his recommendations are in the main safe and simple, and his descriptions of the salient diagnostic points in the few diseases of which he treats are admirable.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 22, 1881.

DR. T. M. MARKOE, PRESIDENT, IN THE CHAIR.

Congenital Dislocation of the Hip.—Dr. C. T. POORE presented a patient, a child seven and a half years of age, who had congenital dislocation of both hips. It existed without assignable cause. The deformity was not noticed until the girl began to walk. Referring to the pathology of this affection, Dr. Poore remarked that there were two classes of cases; the first, that in which the capsule of the joint is very much elongated, and permits of a sliding up and down of the head of the bone; the second, that in which there is no motion permitted by the capsule, and in that form the limb could not be drawn down. In some cases the head of the bone is much diminished in size, and it had been supposed that the dislocation was due to an arrest of development in the head of the bone as well as the malformation of the acetabulum. With regard to treatment, there had been four cases in which it had been said that the affection had been cured. One case was treated by simple extension. Mr. Brodhurst, of London, had divided all of the muscles inserted in the trochanter, and brought down the limb into its proper position, and held it there, and the patient went about without an instrument at the end of six months. Mr. Holmes saw Mr. Brodhurst's case, and testifies in regard to its success. In France, cases had been treated by scarifying the point in the pelvis where it was desired that the head of the bone should be placed, and then bringing the head of the femur down to this point, and retaining it there, and it had been said that very good results had been obtained. It had been claimed that the muscles in this class of cases are apt to be atrophied, but the patient which Dr. Poore presented did not illustrate that statement.

Compound Fracture of the Leg.—Dr. ERSKINE MASON read a paper on this subject (which will appear in full in an early number number of the MEDICAL NEWS), in which he considered especially the period of time required for repair of compound fracture of one or both bones of the leg, as well as the method of treatment according to his own experience. He had had thirty cases of which he had complete notes from the time of the accident up to the date of their discharge from the hospital. In reviewing the notes of the cases which he had met in his private practice, about the same results had been obtained. He had used almost every variety of splint, and finally reached the conclusion that the plaster-of-Paris dressing, in some one of its varieties, with or without brackets, met the indications in the majority of cases, applied either early or late, better than any other appliance. He had used "through-drainage," in connection with the plaster-of-Paris splint, and it had become with him a favorite mode of treatment. The results which he had obtained had been better than those which usually followed the old practice of sealing the wound. Dr. Mason then spoke of the too free use of the drainage-tube, or at least its too early introduction. His observation in these cases had also led him to believe that we might have too implicit faith in antiseptic dressings, at times, and attempt to save limbs which results proved should have been condemned to amputation.

Of the thirty cases, there was fracture of the tibia in sixteen; of the fibula, in three; of both bones, in eleven. In seven cases amputation was required, primarily in five, of which three recovered and two died; secondarily in two, and both recovered. Eighteen cases were treated by plaster-of-Paris dressings, either by the bandage alone, or assisted and strengthened by brackets. Of these, nine were put up at once, and nine were dressed after the lapse of some days, the average period of treatment being twenty-four days. In the cases in which plaster was applied immediately after the accident, the average period of removal of the dressing was twenty-four days, and in the other cases thirty-eight days. Among the eighteen cases, there were four deaths; one from pyæmia on the eighth day; one from shock, the patient dying on the forty-first day; one from alcoholism on the seventh day; one from erysipelas, death occurring on the sixty-first day. The average duration of the treatment was eighty-two days. Four cases were treated by "through-drainage." The average duration was forty-nine days. Several other cases were treated by the same method, and his impression was that they had all done well. Some of the cases had been treated by Volkmann's posterior tin splint with jute, and the average duration of the treatment was sixty days. Of these, there were two deaths; one of pleuro-pneumonia and septicæmia on the eighth day, and one of erysipelas on the seventy-eighth day.

Dr. POST asked whether fracture involving the tibia without the fibula in sixteen out of thirty cases was not an unusual proportion.

Dr. LITTLE remarked that, with fracture involving the lower third of the tibia, fracture of the fibula at the junction of the middle and upper third also took place in the majority of cases, consequently the fracture of the fibula was well covered with muscles and frequently

escaped notice. He suggested that that fact might possibly have obtained in some of Dr. Mason's cases.

Dr. MASON remarked that that point was taken into consideration; that he examined all of the cases himself, and there was no fracture of the fibula.

Dr. POST asked if, according to the experience of the members, it was usual for the fibula to share the fate of the tibia.

Dr. SANDS said that his experience accorded with that given by Dr. Little.

Dr. W. T. BULL remarked that fracture by direct violence frequently involved the tibia without implicating the fibula. He had seen three or four such cases. Again, fracture produced by heavy weights falling upon the limb, might fracture the tibia without involving the fibula. He thought that in a fair proportion of the fractures produced by direct violence, the tibia alone, without the fibula, was involved.

The PRESIDENT remarked that his impression was that the proportion, as it appeared in Dr. Mason's paper, was placed much too high, and suggested that it might be apparent rather than real, from the fact that the fracture of the tibia might have been reported as compound, and that of the fibula as simple.

Dr. YALE suggested that the cases reported by Dr. Mason were only those of which he had complete notes, and, therefore, it may have occurred that in those there was fracture of the tibia only.

Dr. J. L. LITTLE believed that his success in the treatment of compound fractures during the last twenty years, had been due especially to the use of a fixed apparatus, so that the limb could be dressed at any time without disturbing the fragments. That method of treatment he learned in the New York Hospital. Before he introduced the plaster-of-Paris dressing, the ordinary method of treating compound fractures was by the use of the fracture-box with bran, which permitted the fragments to move upon each other every time the limb was removed from the box for the purpose of renewing the dressings. After the introduction of plaster-of-Paris, he treated a large number of cases by the use of the posterior plaster-of-Paris splint, which left the anterior portion of the limb uncovered, a piece being cut out so as to expose the wound, and then the limb was placed in a fracture-box. To prevent pus from running between the splint and the limb, he applied a piece of oiled silk, which was made to adhere to the limb by the application of collodion, and made a little trough through which the pus could flow, and not enter the fracture-box. Under such treatment, the limbs did better than under the old plan of treatment, by the use of only the fracture-box and bran. During the last few years, he had added to that mode of dressing the limb the antiseptic method, and under the combined treatment, his cases of fracture had uniformly done well. He retains the limb in the fracture-box not more than a week or ten days, if the case does well, when it is removed, and a new plaster splint and bandage is applied, and the patient is allowed to sit up and support the limb upon a chair. He had uniformly used Lister's dressing up to about six weeks ago, when he had a case of compound fracture of the leg, in which the tibia protruded through the clothes so as to be seen upon the outside. In that case, after reducing the fragments, he injected the wound with a solution of carbolic acid, one to fifty, then covered it with borated cotton saturated with the same, and over the whole he placed ordinary cotton and secured it with a bandage. The limb was then tied up in a pillow, and a straight splint applied upon either side of the pillow, and it remained in this temporary dressing for four days, during which time there was no rise of temperature, and no discharge appeared through the dressings. He then removed the dressings, and applied a plaster-of-Paris splint; dressed the wound again with borated cotton and carbolic acid, which had been continued up to the present time, and there had been no bad symptoms whatever, except at the end of fourteen days, when some displacement took place accidentally, and there was slight inflammation about the wound. There was, however, no rise of temperature, and no chill, and the patient, who was a man sixty years of age, at the present time was doing well.

Dr. BRIDDON thought that the fracture-box had been discarded altogether. He could not conceive of a more painful plan of treatment. He advised the application of the plaster-of-Paris dressing immediately, introducing a drainage-tube, covering the wound with thick pads of oakum, and suspending the limb in a sling. This method of treatment he thought was much more comfortable than the use of the fracture-box. He certainly believed, with Dr. Little, that the means which obviated the necessity for frequent change of dressing were the best.

Dr. LITTLE said that he had always condemned the plaster-of-Paris *bandage* in the treatment of recent fractures. He was well aware that experts could apply such a dressing without danger, but for the ordinary practitioner, he thought that the use of the plaster-of-Paris bandage was always attended with a great deal of danger, such as might arise from interruption of circulation and consequent gangrene. On the contrary, the plaster-of-Paris *splint*, which he used, leaves the limb open upon its anterior aspect entirely, and it is almost impossible to have obstruction to the circulation occur as a result.

Dr. POST believed that in compound fractures, attended with severe injury to the soft parts, it was safer to place the limb in a fracture-box than it was to put it up immediately in an immovable apparatus. He believed that he had seen cases of gangrene which were due to the fact that the limb had been placed in an immovable apparatus at once, and that the limb could have been saved had it not been subjected to such pressure. The fracture-box with bran possessed the advantage of giving equable support without producing undue pressure upon any part of the limb.

Dr. BRIDDON said that he could accept Dr. Little's treatment by the use of the posterior splint, as it was about as serviceable as the plaster-of-Paris bandage, but he could not see the necessity of putting the limb in a fracture-box.

Dr. LITTLE thought that it was easier to put the limb in a fracture-box than it was to put it in a sling.

Dr. W. T. BULL had abstained from the use of the plaster-of-Paris bandage where it was necessary to frequently change the antiseptic dressings during the first two weeks, inasmuch as it would be laborious to remove and reapply the plaster dressing every three or four days. Again, he thought that the drainage-tube should be withdrawn after the period of granulation had been reached, and the wound treated openly. Then the limb might be placed in a plaster-of-Paris splint, and the dressings applied to the wound through a fenestrum. Previous to that stage, he had almost always used Volkmann's posterior tin splint, and suspended the limb in an iron cradle.

Dr. BRIDDON thought the danger of gangrene from pressure, mentioned by Dr. Post, incident to local swelling of the limb, could be obviated by using cotton-wool very thick next the limb, and over that applying the plaster-of-Paris bandage.

Dr. POST remarked, with regard to drainage-tubes, that he had known mischief to be done by their acting as foreign bodies when retained too long in the wound.

Dr. LITTLE said that Volkmann, at the London International Medical Congress, referred to the fact that drainage-tubes had been permitted to remain in various

parts of the body without producing any irritation, and it subsequently became necessary to cut them out.

Dr. POST had known indurated sinuses to be the result of leaving them in position too long.

The PRESIDENT asked Dr. Mason what his impression was with reference to sealing the wounds in compound fracture, after the old plan, which might be called Sir Astley Cooper's method, as compared with covering them with antiseptic dressings.

Dr. MASON replied that his experience had been limited to five cases; two of the leg, two of the thigh, and one of both bones of the forearm. In those cases the strict antiseptic dressing was used, and he believed the wounds closed sooner than they would have done under the old plan of sealing the wounds with collodion and cotton. He was satisfied that the antiseptic dressings gave the best results.

Dr. YALE referred to one case of compound fracture of the leg, in which the Lister dressing was applied to the wound, and in less than ten days it was removed, and the case was treated as one of simple fracture.

Dr. BULL thought that the surgeon might be guided somewhat by two considerations; first, the character of the violence; second, the damage done to the soft parts. If the violence was such as did not comminute the bones, and the opening was small, and there was evidence that the soft parts had not been extensively contused, and no great amount of blood had been effused into the tissues, he would prefer to use the antiseptic dressing. To settle these questions, however, was sometimes a matter of considerable difficulty, and required a somewhat varied experience. He had seen perhaps half a dozen compound fractures of the leg, involving both tibia and fibula, where pin-hole wounds of that kind existed, and there was no reason to believe the fracture in the bones was extensive or comminuted, and he had put on the antiseptic dressing, and the result had been entirely satisfactory, and he should prefer it to sealing up the wound in the old-fashioned way.

Dr. SANDS thought that the results of treatment of such cases of compound fracture of the leg were very much better than the results obtained ten or fifteen years ago at the New York Hospital. In those days it was rather expected that complications would ensue in such cases; but, at the present time, serious inflammation or septic infection seldom occurred during the treatment of a compound fracture. In the Roosevelt Hospital there were now three cases of compound fracture of the leg, treated simply by washing out the wound with carbolic acid, and then covering it with antiseptic dressings; in two of these the wounds had closed entirely, and in the other, although the wound was not completely healed, it was nearly so, and no bad symptoms had at any time been developed. He had no doubt whatever that the antiseptic plan of treatment gave much more favorable results than the old-fashioned practice of sealing the wound.

Dr. LITTLE said that at St. Vincent's Hospital a large number of cases of compound fracture were treated, and the rule was always to wash out the wound with carbolic acid and apply an antiseptic dressing, and it had now been four or five years since he had seen a case of compound fracture in which there had been discharge sufficient to penetrate the dressings; certainly he had not met with a case in which it became necessary to make a counter-opening to afford exit for pus.

Dr. POST referred to a compound fracture of the leg, situated in the immediate vicinity of the ankle-joint. The bones were badly comminuted, and the soft parts were extensively lacerated. He attempted to save the limb. He washed the wounds thoroughly with carbolic lotion, inserted drainage-tubes, and put up the limb in a plaster-of-Paris apparatus, and for several days there were good prospects for saving it; gangrene, however, occurred, and amputation became necessary. The patient died on the following day of tetanus.

Dr. MASON asked Dr. Little if, in the treatment of cases of compound fracture at St. Vincent's Hospital, drainage-tubes were used.

Dr. LITTLE said they were very rarely introduced.

Dr. LANGE thought it was especially important in cases of compound fracture to consider whether or not the wound was already infected. If the wound was perfectly fresh and without infection, antiseptic dressing might be applied simply to prevent infection, but if infection was already present, then the application of an antiseptic dressing alone could not prevent inflammation. In the latter class, disinfection of the wound should first be made, and each case must be treated according to its special features. He thought it was according to common experience in compound fractures that large, open, external wounds were not so dangerous as those of moderate or small size, with extensive injury to the soft parts and the bone inside. Therefore, it was important to decide, with reference to every surgical wound or injury, how extensive had been the injury to the bone or the soft parts, whether a great deal of tension and swelling was to be expected, and how profuse the discharge would probably be, and if the circumstances were such that a profuse discharge was to be expected or such loss of vitality in the parts as is favorable to the development of inflammation or decomposition, as free exit for it as possible must be maintained. With a view to prevent inflammation in a case of compound fracture, or if inflammation was present to counteract it, immobilization must above all other things be observed. It must, however, be kept in mind that through immobilization we prevent inflammation in so far only as we avoid that condition of tissues in which they represent a more favorable soil to the development of inflammation. Inflammation in compound fractures in most cases was infection from without. Immobilization had been practised long ago. The good results, however, dated since that comparatively recent period when surgeons learned to combine it with strict antiseptic measures. Listerism, of course, had not the monopoly for the latter, although it was a very efficient method. Antiseptic procedures, however, were indispensable for good results in compound fractures, and it was more than probable that all kinds of successful treatment owed their efficacy to their antiseptic qualities. It was only necessary to state what constitutes the latter.

Dr. SANDS remarked that the difficulty hinted at by Dr. Lange was an objection to the employment, as a general rule, of the plaster-of-Paris splint, which envelops the limb except where it is exposed at the situation of the fenestra. The advantage of the plaster-of-Paris splint in simple fracture, is the immobility of the limb which it secures, preventing thereby pain and injury of the soft parts caused by movement of the fractured ends of the bone. If this end could be accomplished after compound fracture, the use of the splint would be equally advantageous as in a simple fracture, but he thought that this was rarely the case. If the plaster-of-Paris splint was applied with sufficient pressure to secure immobility, we expose the patient to the risk of mischief resulting from swelling, and may be obliged to remove the plaster-of-Paris splint after the lapse of a few hours or days. If, on the other hand, to avoid this danger liable to arise from swelling of the limb, we put it up loosely, or insert large pads of cotton, as suggested by Dr. Briddon, we shall find, if no swelling takes place, that the limb will soon be too loose, and the dressing will rather cover the limb than keep the fractured bones in position. Another objection to the use of the plaster-of-Paris splint in compound

fractures of the leg, was the difficulty, unless the fenestra was exceedingly large, of applying efficient antiseptic dressings. For this reason he had followed the practice adopted by Dr. Bull. Volkmann's posterior splint gave adequate support to the limb, while it left the anterior part, where the wound in the skin usually existed, open for inspection, and allowed the application of antiseptic dressings without much disturbance of the fractured bones. Furthermore, it allowed the application of the bandage over the limb with just such an amount of pressure as was necessary to give proper support. He should, therefore, defer the employment of the plaster-of-Paris splint until all inflammatory swelling had subsided, when he thought it could be used with the best results.

Dr. LITTLE thought it a good plan to make a distinction between the plaster-of-Paris *bandage* and the plaster-of-Paris *splint*. The plaster-of-Paris bandage was a dressing which enveloped the limb entirely, whereas the plaster-of-Paris splint was an apparatus which could be applied to the posterior aspect of the limb, and did not render the limb liable to be injured from obstruction to the circulation, and, at the same time, it rendered the fractured bones immovable, and allowed them to be inspected at pleasure.

Division of the Tendon of the Flexor Profundus Digitorum.—Dr. POST narrated a case as follows: A male patient presented himself at his clinic, who, two months before, had wounded the palm of the left hand very nearly in front of the articulation of the first phalanx of the ring finger with the metacarpal bone. After that injury he was able to flex the finger with the other fingers for three days, and then suddenly, after tossing a child, something gave way in the finger, and he lost the power of flexing it entirely. After the lapse of two months the wound had healed entirely, and passive motion could be made, but the patient had no voluntary power over it. It was evident that there was division of both tendons belonging to that finger. Dr. Post made an incision down to the sheath of the tendon, which he divided, and found the distal end of the tendon lying loose in the sheath, entirely separated from the proximal end, and division had taken place just at the point where the tendon of the flexor profundus passes through the slit in the flexor sublimis. He found that the end of the tendon of the flexor profundus was smooth and rounded, and there were little rounded bulbs in the incision of the tendon of the flexor sublimis. He then extended the incision to the extent of about three centimetres, but was not able to find the proximal end of the tendon. He believed that there was incomplete division of the tendon at the time of the injury, and that the separation became complete at the time when the patient felt something give way in the palm of the hand three days afterward. The case was interesting, from the fact that the division was not perfect at the time of the receipt of the injury, and from the fact that there was such a wide separation of the ends of the tendon. A carbolic lotion was applied to the wound, and no unfavorable symptoms had followed the operation.

Dr. SANDS remarked that he had been similarly disappointed in such an operation, and he also had the impression that, as a rule, the separation of divided pieces of tendon was so great as to discourage any attempt to replace the parts after the lapse of any considerable period of time.

The PRESIDENT remarked that he had had the same experience in divisions of the tendons of the fingers.

Dr. POST remarked that when the tendon was within the sheath, it probably receded more than when elsewhere.

Dr. LITTLE remarked that he failed to reach the proximal end of the tendon in a case immediately after the injury.

Vesical Calculus. Bigelow's Operation.—Dr. LITTLE presented the fragments of a vesical calculus removed by rapid lithotrity, with the following history: A man, sixty-three years of age, a patient of Dr. A. H. Smith, had suffered from frequent micturition for six months. Symptoms of stone developed four weeks before he saw the patient. The patient was etherized, and Bigelow's medium-sized lithotrite was introduced. The stone was seized and crushed, and the fragments removed through the evacuating-tube, and the bladder irrigated until no further fragments could be found. The operation lasted only fourteen minutes. Before the operation, the patient was obliged to pass water every hour; after the operation, he could hold his urine for six or eight hours. Not the slightest unpleasant symptoms followed the operation.

Sequestrum from the Sternum.—Dr. POST presented a small sequestrum removed from the upper part of the sternum. The patient was a woman, forty-five years of age, who was under his care in the Presbyterian Hospital in August. She had had caries of the sternum for some time. He then removed portions of dead bone, and an opening was made extending into the anterior mediastinal space. The finger could be passed behind the sternum without unpleasant consequences following. She left the hospital, but subsequently came under his observation, and he found, on inspecting the wound, a piece of bone present at the deeper part of the cavity, which he seized with a pair of forceps and extracted, and it was the specimen presented. Since that time the sore had granulated, and the parts looked as if recovery would take place. There was no distinct syphilitic history in the case. The specimen was interesting, from the fact that it was a sequestrum from a spongy bone.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting November 7, 1881.

S. D. GROSS, M. D., PRESIDENT, IN THE CHAIR.

Aneurism of the Femoral Artery Cured by Pressure.—Dr. S. W. GROSS exhibited a case, which he said was really under the treatment of Dr. S. D. GROSS, the President, with the following history:

About a year ago, a colored hod-carrier, aged twenty-seven years, began to suffer from a constant dull, aching pain in the left knee, which he attributed to rheumatism, and which was increased by hard work. Four months prior to his admission into the Jefferson Medical College Hospital, he noticed a beating just above the middle of the thigh, and he found at this point a rather soft pulsating swelling, about the size of a common marble. On admission, there was an aneurism of the superficial femoral artery at the apex of Scarpa's space as large as the fist, and the pain was still present in the knee. There was no history of syphilis, but he fell from a ladder and bruised the corresponding leg a few months previous to the appearance of the tumor.

On the 7th of October, pressure was maintained for three hours upon the common femoral artery by means of a pestle, when it was discontinued on account of the severe pain which it produced. On the 9th of October, the same measure was employed for five hours, but without any benefit. Four days subsequently, two five-pound bags of small shot and a leaden weight of ten pounds were applied to the artery and the circulation completely controlled. The constant movements of the abdominal muscles in respiration, and the restlessness of the patient rendered it necessary to hold the weights in place, and at times to make slight pressure with the hand to overcome the pulsation. At the expiration of an hour and a half, with a view to relieve suffering, one-third of a grain of morphia was thrown under the skin, and the dose was repeated in

two hours. At the end of another thirty minutes, or of four hours from the beginning of the treatment, all pulsation had ceased in the tumor, which had become hard and firm; but the compression was maintained for five hours longer as a matter of precaution. After the contents of the sac had consolidated, there was but little suffering and the patient slept most of the time. At the present date, the tumor is diminished one-fourth.

Traumatic Aneurism of the Posterior Tibial Artery.—Dr. JOHN H. PACKARD read the history of this case. Joseph D., æt. eleven years, a sturdy and well-conditioned boy, was admitted into the Episcopal Hospital October 8, 1881, with the following history: Two weeks previous, he had received a blow on the inner side of the left ankle, from a bit of iron thrown by a playmate. The part "swelled a good deal," but the hurt was not thought much of until the day before his admission, when, in his mother's words, "the ankle burst, and he lost a cupful of blood." Dr. Packard's attention was not called to the case until four days after the admission, when he found a small, pulsating tumor, just back of the inner malleolus. The next day he laid the tumor open, and applied two silk ligatures, one above and the other below. Three days afterwards, the bandage became suddenly saturated with blood, and the boy fainted. A compress was firmly applied, and Dr. Packard was summoned. Enlarging the wound somewhat, he found the upper ligature loose, apparently from the cutting through of some areolar tissue included along with the artery. A second ligature was applied, which held until the 18th, somewhat over forty-eight hours, when bleeding again occurred, in the evening. He then exposed the artery a little higher up, and tied it again, at a point about a quarter of an inch above the one previously chosen. After this there was no further trouble; the wound did well, and on the 23d, ten days after the first ligation, and five days after the third, both ligatures were found lying loose. Healing progressed very rapidly, and the boy is ready for discharge.

Hæmorrhage from a Wound of the Facial Artery, in which Ligation was Performed.—Dr. PACKARD related the following history: B. F. Z., æt. twenty-five years, was brought to the Episcopal Hospital on October 27, blanched and much prostrated by bleeding from a wound in the left cheek, about three-quarters of an inch from the angle of the mouth. Another wound about one and a half inches long, just over the edge of the lower jaw, seemed to be at right angles with the facial artery, and had been closed by means of a large pin and a figure-of-eight suture. The man stated that the wounds had been inflicted with a penknife, about ten days previous, and that two severe hæmorrhages had occurred, one on the eighth day, and the other on the evening before his admission. Ether was at once administered; the clots turned out of the upper wound, enlarged for the purpose, and a silk ligature applied to each end of the divided artery. The edges of the skin were then brought together by means of hare-lip sutures, and a wet dressing applied containing a small amount of carbolic acid. Healing took place rapidly, the ligatures coming away on the seventh day.

Arterial Hæmorrhage in a Case of Extensive Burn; Ligation of the Brachial Artery.—Dr. PACKARD also related the case of Hilda A., æt. eighteen, admitted into the hospital during the service of his colleague, Dr. Hunter, September 7, 1881, having sustained, two weeks previously, severe burns from trying to hasten the kindling of a fire by means of coal-oil. Her body and both arms were terribly injured, and when he came on duty, October 1, the process of granulation was going on slowly, while from the irritability of the stomach there was reason to fear serious involvement of that organ, or of the duodenum. This, however, was overcome after a few days, and her condition was greatly improved. On the 4th of November, at his daily visit, the resident surgeon, Dr. Robins, informed him that arterial hæmorrhage had occurred from the left arm, and had been controlled by a compress over the brachial artery. On removing this compress (the patient being etherized), several jets of arterial blood spurted from vessels opening on the granulating surface at the inner part of the arm. He immediately, with his fingers, broke away the tissues at the inner side of the biceps so as to expose the brachial artery at the usual point of ligation, when he applied a silk thread. No further bleeding occurred, and the case has progressed since as if no such alarming incident had threatened to interfere with recovery.

Dr. WM. HUNT recollected a number of cases of spontaneous aneurism in negroes, and inquired whether the disease was more frequent in the black than in the white race. He had recently seen a case of traumatic aneurism of the facial artery, to which Dr. Levis had also been called in haste, which had formed in the course of one day. Dr. Levis and he arrived at the house at the same time. The whole mass was dissected out and the bleeding vessels tied.

Dr. J. M. BARTON spoke of once seeing an aneurism which so resembled an abscess in the cervical region that it had nearly been laid open by the gentleman in attendance. He was deterred, however, by noticing the pulsation. The patient died from rupture of the sac, and the autopsy showed evidence of syphilis. The aneurism was of the carotid artery.

Fracture of the Patella Treated by Hooks.—Dr. T. G. MORTON exhibited a patient who had been under treatment for fracture of right patella. There was used lead water and laudanum for a week, when Dr. Morton's hinged modification of Malgaigne's hooks were applied. The ordinary hooks would not have obtained accurate apposition, since it was necessary to have the upper pair of hooks widely separated; while the lower ones were close together. No irritation followed. It is possible that bony union is favored by the fact that circulation is not interfered with when the hooks are applied, as when tight bandages are adjusted. The slight irritation due to the insertion of the points may increase the tendency to throwing out of callus for the bond of union. In this case, hooks had remained in position fourteen days.

Dr. PACKARD said he was probably the first surgeon in Philadelphia to apply Malgaigne's hooks.[1] The patient, after having what was thought to be bony union, fell and refractured the bone. There is no danger, as has been supposed by some, of penetrating the joint. He himself now usually employs the method of Sanborn, which consists in loops of adhesive plaster that bring the fragments together by twisting.

Dr. NANCREDE mentioned a case where there was no separation, though crepitus was present. He could just catch his finger-nail between the edges of fragments. Could such a fracture, without laceration of the tendon and fascia, be produced by muscular action?

Dr. HUNT had once treated a patient who had fracture of both bones without any separation. He needed no apparatus, and obtained a good cure.

Dr. WILLARD recently saw a case undoubtedly due to muscular contraction and no separation existed.

The PRESIDENT spoke of the recent successes in wiring old fractures where non-union had occurred; and also referred to the method of passing wire through the ligament of the patella and quadriceps tendon in order to bring parts together without interfering with the joint.

Dr. MORTON called attention to two cases he had

[1] See *American Journal of the Medical Sciences*, April, 1861.

seen; in one the tendon was ruptured above the patella; in the other, below it. No wiring was done. One patient is known to have a good limb for walking, but ascending steps is somewhat difficult.

Dr. WILLARD had had a case where the ligament of the patella was torn close to the tibia, but he had hesitated about using wire.

Dr. PACKARD thought it would be difficult to get a good hold for wiring so close to the bone, and feared trouble might arise from inflammation of the bursa beneath the patellar ligament. He had seen recurring bursitis in this region following injury of the part. Sutures might be better employed in rupture of the quadriceps above the bone.

Supernumerary Thumbs.—Dr. NANCREDE exhibited two supernumerary thumbs removed from two children who had double thumbs on the left hand. The additional digits sprung from the head of the metacarpal bones, and were well formed. There was no hereditary predisposition. A child born between these two presented no malformation.

Dr. MORTON recently saw an Italian infant without ears. There were little nodules on each side of the head, and an indistinctly felt depression under the skin, as though a meatus might exist there.

Urinary Calculi.—Dr. J. H. BRINTON reported the case of a man whom he had sounded three or four times, about eighteen months ago, and failed to find stone, though the rational symptoms were present. Last spring, however, he found stone, and employed Bigelow's rapid lithotrity method, by which a large amount of fragmentary matter was removed. He sent the patient home because the weather was hot, but on his return, this fall, removed over fifty calculi by lateral lithotomy. He stated that he believed Dr. Agnew had once removed about two hundred calculi. The patient he had just referred to was able to fish small calculi out of his own bladder by inserting a soft rubber catheter and entangling the stone in its eye.

The PRESIDENT stated that he had removed as many as fifty-four calculi, and that Physick had extracted nearly one thousand at one operation.

Cheap Water-Bed to Prevent Bed Sores.—Dr. MORTON mentioned the use at the Pennsylvania Hospital for the Insane of water-beds, made by stretching a piece of gum cloth over a shallow trough. Drs. LEVIS and MEARS also spoke of the cheapness and advantages of this substitute for rubber mattresses filled with water, which they had seen used in other cities.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 24, 1881.

FORDYCE BARKER, M.D., PRESIDENT, IN THE CHAIR.

The Cell Doctrine and the Bioplasm Doctrine.—Dr. LOUIS ELSBERG read a paper with this title. He stated that last May, at a meeting of the Laryngological Association, he presented an account of some histological investigations of the cartilages of the larynx, and, as the structure of hyaline cartilage has an important bearing on the subject of his paper, he gave a brief résumé of the views then advanced. As the result of his investigations, Dr. Elsberg is not only able to confirm the views of Heitzman and others, that there are cilia-like offshoots or prolongations of the substance of the cartilage corpuscles penetrating into the basis substance, but has been able to satisfy himself that these offshoots form an interconnecting reticulum through the basis substance, and that there exist in this network masses of living matter. Hyaline cartilage is, therefore, a mass of living matter, in which blocks of basis substance are imbedded; and the author believes that the communication of these protoplasmic processes with each other and with the surrounding tissues permit the processes of nutrition to be carried on without the assumption of "juice canals."

Pyæmic Parotitis.—Dr. CHARLES A. LEALE read a paper on this subject, and presented two of the patients on whom he had operated, one showing complete loss of the gland from suppuration, the other adhesions at the cheek over the duct of Steno. The latter case subsequently had goitre, which was treated successfully by the internal and external use of iodine.

Dr. Leale differed from the numerous writers who thought that suppuration of the parotid arose from a mechanical occlusion of the *ductus Stenonianus*, as a result of dryness of the mucous membrane of the mouth, and stated that his observations led him to believe that when it occurred in any of the enteric fevers, dysentery, or osteo-myelitis, it always arose from systemic poisoning from an ulceration of such a low grade where constitutional changes were constantly going on, that the glands of the body exerted their influence to eliminate the materies morbi, and therefore metastatic abscesses of the parotid, liver, lungs, brain, etc., were formed. As to the frequency of suppuration of the parotid, he stated that statistics showed it to be a not very uncommon disease, as Hoffman gives 16 cases in about 1600 typhoid fever patients, and subsequently, after the employment of the antipyretic treatment, 1 case occurred in every 550, or 2 in 1100 patients, both of which terminated fatally. In illustration of this disease, when suppuration of the parotid occurs, he gave the history of four cases: one from pelvic cellulitis, one from ulceration of the bowels in typhoid fever, one from general ulceration of the mouth and stomach, and one from suppuration of the kidneys following an acute attack of degenerative nephritis; and, in the same connection, gave the history of two cases of metastatic abscesses of the liver as illustrative of the same provoking cause.

He had never seen a case of pyæmic suppuration of the parotid end in recovery when the pus was not permitted an exit. In three of his cases he had opened by incision and in the other profuse discharge of pus ran from the ears for a period of seven months, the discharge coming through the perforations from the middle ear. In one case only had he seen perforation of the floor of the cartilage of the external auditory canal, and that was one of the patients exhibited to the Academy, who showed the deformity resulting from the complete loss of the gland, resulting in a large cavity under the angle of the jaw.

In explanation of the modus operandi of this exit through this firm cartilage, Dr. Leale thought pressure could accomplish this result, as the gland is so firmly bound down by dense fascia. If a small aneurismal tumor can produce perforation of the dense, loosely-attached œsophagus, and cause fatal hæmorrhage into the stomach, a specimen such as he had presented to the New York Pathological Society, why not perforate a cartilage held so firmly in place?

The first case shown was a lady, who at the age of forty-one years had a metastatic abscess of the parotid gland, with discharge of pus through an opening into the cartilage at the floor of the external auditory canal. Complete destruction by suppuration of the entire parotid gland followed, producing a permanent deformity on that side of the neck with a deep hollow beneath and under the angle of the jaw. This lady had an attack of general peritonitis and pelvic cellulitis, and death was nearly caused by suffocation in consequence of pressure on the pharynx. Dr. Leale opened the pharyngeal abscess, and then had through and through drainage; the director inserted just above the angle of the jaw could be pushed through the parotid gland and felt with the finger in the throat.

In this instance the cerebral symptoms were very

profound, complete blindness, deafness, delirium, and slight opisthotonos, showing that the disease had extended to the base of the brain. The temperature ran up on several occasions to 106° F. The convalescence was long, and for months the severe attacks of cephalalgia rendered life miserable. She can now see fairly, and hears nearly as well as ever. Since her attack she has never had a day free from pain, and will probably continue to have pain for several years. The treatment in her case was by iodide of potassium and tonics.

In the second patient the parotid abscess followed a very severe attack of typhoid fever, the parotid was opened under the lobule of the ear, where the duct of Steno was occluded, and when Nature had made an effort to form a spontaneous opening on the cheek.

Our attention is generally drawn to pyæmic parotitis by an earache, which on examination is found to be associated with great pain on pressure under the lobule of the ear, and to extend beneath the angle of the jaw, along the course of the gland. We find hyperæmia, and within twelve hours parenchymatous infiltration, consequent enlargement and œdema; this proceeds gradually until the end of the third or fourth day, when, as a rule, minute abscesses will form in the structure of the gland, either to increase, to coalesce and form one large parotid abscess, or, when the vital forces are nearly exhausted, to remain as numerous multiple abscesses showing a low grade of inflammation.

We may expect metastatic abscesses in osteo-myelitis, and Dr. Leale gave an illustration where, after an amputation of the arm and complete healing of the stump, inflammation within the Haversian canals and in the cancellated tissue of bone occurred, ending in death by cardiac thrombosis. At the necropsy there was found a large abscess in the liver. The centre of the bone above the amputation was also filled with minute abscesses. This patient had presented all the symptoms of acute pyæmia, had recently returned from a malarial district, and his symptoms much resembled the low grade of remittent fever. The end of the stump kept well until within a few hours of death.

A remarkable illustration was brought forward showing the connection of metastatic abscess and osteo-myelitis, and demonstrating, in the first place, the impossibility for the surgeon at times to prevent the occurrence of inflammation of the cancellated structure of bone after certain gunshot injuries, and secondly, that even in primary union of the flesh, when hermetically closing of the wound immediately follows, the sepsis may be lodged on a ball before it entered the body, and be deposited as it passes through the bony structure, there to commence an ineradicable infection sufficient to produce ulcerative softening whereby the entire system becomes infected, a metastatic abscess follows, and death inevitably ensues. Dr. Leale considered such a wound a mortal one, although others might escape with much more serious injuries, yet in this instance the ball caused the injury to the bone, and at the same time deposited a septic poison, impossible for the powers of nature to overcome or the surgeon to reach. Even when the affected bone could be removed by subsequent operation, he had seen the disease reappear in other parts, and in the end cause death.

The two illustrative cases noticed were observed by him while Assistant Surgeon U. S. V. One was Captain C——, who came under his observation April 16, 1865. He had been wounded an inch above the elbow-joint by a ball fracturing the humerus. The limb was amputated in the middle third by the flap method, and had entirely healed. The patient was apparently well, and was told there was no necessity for him remaining in hospital. He was permitted, however, to remain for a rest for a few days, but twenty-two days after his admittance he died of pyæmia. At the necropsy, Dr. Leale found osteo-myelitis of the stump-bone and a large metastatic abscess in the liver. In the second case, after the discovery of osteo-myelitis, a second amputation did not check the disease, and death occurred. Metastatic abscesses were found at the autopsy.

NEW INVENTIONS.

An Apparatus for Weight and Pulley Extension.

Dr. Frederick C. Sheppard, Surgeon to the Children's Hospital Dispensary, Philadelphia, has devised an ingenious form of apparatus for weight and pulley extension, which admits of application to the ordinary bedstead. The two forms of apparatus shown in the accompanying cuts were designed for use in the treatment of diseases or injuries of the lower extremity requiring confinement to bed and extension by weight and pulley.

That shown in Fig. 1 is intended for cribs or beds with high foot-pieces, and consists of four rods, *a*, *a*, *a*, *a*, joined at the ends, forming a parallelogram, to the upper corners of which are affixed two hooks, *g*, *g*, by which it is suspended from the upper bar of the foot-piece. A curved rod, *d*, bearing a wheel, *e*, surmounted

Fig. 1.

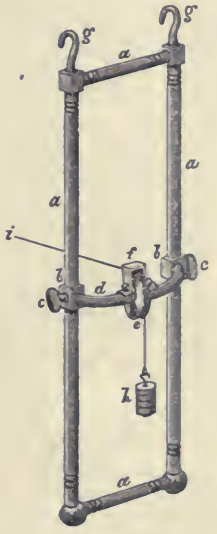

Fig. 2.

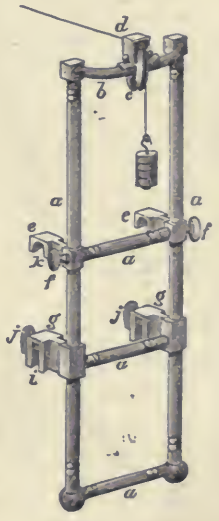

by a guard, *f*, slides by means of the attachments, *b*, *b*, upon the two vertical bars, *a*, *a*, and can be adjusted to any desired height by the set-screws, *c*, *c*. A flexible metallic or other cord, attached at one end to the stirrup on the limb of the patient, and at the other to a weight, *k*, passes over the wheel, *e*, and is prevented from slipping off by the guard, *f*.

Fig. 2 represents the apparatus adapted to the ordinary iron hospital bedstead. In it the whole framework can be elevated or depressed. The slots, *k*, *k*, fix the attachment, *e*, *e*, to the upper bar of the foot-piece, while the attachment, *g*, *g*, is firmly clamped to the lower bar by the slots, *i*, *i*, and the set-screws, *j*, *j*. The frame being adjusted to the required height is retained in position by the set-screws, *f*, *f*. The curved rod, *b*, bearing the wheel, *c*, and the guard, *d*, is the same as in Fig. 1, except that instead of sliding, it is permanently attached to the upper portion of the frame.

The material used in the construction is polished brass, which gives an ornamental effect. A number of these apparatus were made by Messrs. Gibson, Shaw & Co., of this city, and have been used with satisfaction in the Children's Hospital for upwards of two years.

CORRESPONDENCE.

WAS THE THORACIC DUCT INJURED IN THE CASE OF PRESIDENT GARFIELD?

To the Editor of The Medical News:

SIR: It is a curious feature in some of the criticisms and comments on the President's case, that, in view of the ante-mortem symptoms and the post-mortem examination, it should have been asserted that the "rapid emaciation and mal-nutrition" were due to a wound of the thoracic duct. As distinguished a surgeon as Dr. Wm. Hunt says (*Medical News and Abstract*, November, 1881): "There was the origin of the thoracic duct, with its receptaculum chyli, right in the line of the wound; hence, the rapid emaciation, and the other nutritive disabilities, further explained by disturbance of the sympathetic trunks and ganglia."

The official record of the post-mortem examination (*American Journal of the Medical Sciences*, October, 1881), shows, by statement and diagram, the track of the ball in the spinal column to have been by a small aperture of entrance, one-quarter of an inch distant from the intervertebral foramen of the twelfth dorsal and first lumbar vertebræ, and the centre of the foramen of exit to lie one-half an inch to the left of the median line. With a view to a determination of the exact relations of the parts, I have made, within the past week, two dissections at the University of Pennsylvania, studying with especial care the thoracic duct and receptaculum chyli, and the structures immediately adjacent.

The following is a summary of my observations. The receptaculum lay in one case directly upon the median line, in the other about a line to the right of the median line, closely applied to the body of the second lumbar vertebra, commencing in a pouch at its inferior border, and tapering upwards and to the right, to terminate as the thoracic duct at the lower border of the first lumbar vertebra. The thoracic duct then applied itself closely to the right crus of the diaphragm, and passed up through the aortic opening. The whole of this structure was efficiently protected, anteriorly and to the left by the abdominal aorta, and to the right by the vena cava.

Spicules of bone could not then have reached it from either side, where it was protected by more important organs; and to have been injured posteriorly requires the supposition of more extensive injury to the vertebra than has been stated.

The following summary of symptoms present in the six recorded cases of wound of the thoracic duct, is given by Bradley ("Injuries and Diseases of the Lymphatic System," London, 1879), and is of interest in connection with the study of this historic case.

"Hoffmann's first case was that of a woman wounded through the left side with a knife. Following the wound there was a copious discharge of a spontaneously coagulating fluid, which was observed to be milky during digestion, and clear while the patient was fasting. In his second case, the escape of chyle followed the opening of an abscess of the posterior mediastinum. Monro relates a case where the thoracic duct was wounded by a stab; the lymph escaped externally and also into the pleural cavity, interfering with the heart's action. Guiffort's case is of a similar nature. Bonnet gives the history of a Baron Heinden, who was wounded in battle by a bullet, which escaped beneath the left scapula. From this wound there gradually began to flow an excessive quantity of lymph, 'tanta in copia effluxisse, ut non solum lintea quintuplicata, indusium lodicesque imbuerit, sed quoque limbos inundaverit.' The patient lived for several months, dying at last of exhaustion." In Quincke's case, "the pleural cavity became so full of extravasated lymph that paracentesis had to be performed to prevent suffocation, from which, indeed, the patient eventually died."

It will be seen from the above, that a stillicidium of lymph, generally in great quantities, is the *invariable* attendant of wounds of this nature. The fact that this symptom was wanting, so far as we know, in the President's case, precludes, with even greater certainty than the anatomical considerations, the possibility of any injury to this most important organ.

I am, sir, yours, etc.,

HOWARD ATWOOD KELLY.

PHILADELPHIA, 323 South Seventeenth Street.

NEWS ITEMS.

NEW YORK.

(*From our Special Correspondent.*)

PROSECUTIONS UNDER THE MEDICAL ACT.—The report of the Board of Censors of the Medical Society of the County of New York, read at the last annual meeting, gives a detailed account of the work done in the attempt made to enforce the medical law of 1880, which requires the registration of practising physicians in the county, and the prosecution of illegal practitioners. Several quacks were prosecuted, but only one of them was fined, one Abraham E. Cox, who was practising under a diploma improperly obtained from the defunct "Castleton Medical School," in Vermont. The fine imposed was $100. Another "irregular," the charge against whom was the practising under a diploma illegally obtained from an Eclectic School in this city was, upon his preliminary examination, found unable to speak English. How he passed the examination for his degree he could not tell. This case was presented to the Grand Jury for indictment, but this sapient body declined to consider the case, and refused to examine the Society's witnesses; indeed, one wiseacre informed the President of the County Society, Dr. A. E. M. Purdy, that there was no need for a physician to have a diploma. A third, a man named Dr. Kraft, who registered as a graduate of the Electro-Therapeutic Institute of Philadelphia (whatever that is), escaped on the ground that he cured by electricity and magnetism only, and used no drugs. The Justice held that he was not a medical practitioner, under the statute, and dismissed the case.

Many more cases are to be prosecuted, and one among them promises to be important and interesting. The charge made is perjury, and the penalty is the State prison. The accused, as is clearly shown, obtained his diploma illegally from a defunct medical college of this city, and the Society proposes to test the section of the act which relates to false swearing. Another remarkable diploma was issued from the American University of Philadelphia (Buchanan's diploma mill), on the 4th of July, 1876, palpably illegal. The owner, one "Dr. Grindle," has been arrested, and is held to explain why he has not had his diploma endorsed according to law, coming as it does from a school without the State. After that he will have a chance to tell how he happened to graduate on the National holiday. The Society evidently is in earnest, and is determined to rid New York city of these irregular and dangerous humbugs.

A NEW SOCIETY has been formed, called the Materia Medica Society, which discusses the nature and action of drugs. If anything can be predicated from the few meetings already held, the society promises to be a useful one, as the papers presented have been of a high standard, evincing a good knowledge of the subjects discussed. A novel feature is the one relating to the admission of new members. Each candidate must pre-

sent a written thesis upon some subject in materia medica as a proof of his qualification for membership, and upon that proof he is admitted or rejected. A similar rule has been in operation in the New York Dermatological Society for some time past.

BOSTON.

(From our Special Correspondent.)

THE SUFFOLK DISTRICT MEDICAL SOCIETY, which includes all members of the Massachusetts Medical Society residing in Boston, last winter dispensed with half of its monthly meetings and formed from among its members sections devoted to special branches of medicine. The sections devoted to general medicine and to surgery have held several meetings, with good attendance, and far more animated discussions than under the old plan. The section of Obstetrics and Diseases of Women will soon be formed; others will follow if the scheme proves satisfactory.

A MEDICAL MAYOR.—Dr. Samuel A. Green, city physician of Boston, has received the nomination for mayor of both the Republican and Citizens' Conventions. This conjoint action will, it is believed, ensure his election despite the fact that the Democratic candidate generally carries the election by a small majority.

HARVARD MEDICAL SCHOOL.—The new building for the Harvard Medical School has reached the third story. The work will probably be stopped for the winter on December 1st. The fund raised for the erection of the building amounts to $300,000.

The total number of students enrolled this winter is 243, divided as follows: Graduate's Course, 9; Fourth Class Course, 10 (optional); Third Class Course, 80; Second Class Course, 63; First Class Course, 81.

Prof. Calvin Ellis, Dean of the Faculty, who has been incapacitated by ill health from lecturing or practising for nearly a year, is reported to be convalescing.

BALTIMORE.

(From our Special Correspondent.)

THE BACILLUS LEPRÆ.—The recent descriptions of Neisser, Eklund, and others, of the bacillus lepræ, first observed by Hansen, have awakened widespread interest in the pathology of leprosy. Dr. I. Bermann, of this city, has been able to detect the presence of the bacillus in leprous tissue, and to confirm the discoveries of the above-mentioned authors. Sections exhibiting the bacillus were shown at the recent meeting of the American Dermatological Association at Newport. Since then, Dr. Bermann has improved his methods of preparation and investigation, and is now able to demonstrate the bacillus to perfection. His results were shown at a recent meeting of the Baltimore Clinical Society. The directions given by Neisser for detecting the little organisms enable one to recognize them, but not with satisfaction. Weigert's methods for investigating bacteria answer the purpose perfectly. The affinity of the bacillus lepræ for the aniline violet staining fluid is remarkable. By immersing the stained sections in oil of cloves for forty-eight hours, the violet color is removed almost completely from the tissues, leaving the bacilli stained dark purple and presenting sharp outlines. It remains very difficult to see them, however, even after this preparation, and objectives of high power (with small angle) must be employed. By using, as a condenser, an objective of about one-quarter inch, for illumination, they come out with splendid definition. The bacilli are mostly to be found in the protoplasm of the cells, but may be seen elsewhere. Sections thus prepared and examined will satisfy the most incredulous. Dr. Bermann has been the first in this country, we believe, to detect the bacillus, and will shortly publish his observations in full.

CHARLESTON.

(From our Special Correspondent.)

SCARLET FEVER, after a reign of several months, has wholly departed from this city. Diseases like this are more infectious than contagious. They do not come, stay, or go away by accident. When the scarlet fever disappeared, it was not that it had no more fit subjects to infect; there were constantly fresh arrivals of new children for it to seize upon. Diphtheria has been here much longer, and has not yet left us, as an occasional case testifies. There must be *plus* the infecting poison, without which scarlet fever, diphtheria, small-pox, or measles cannot exist, some climatic, telluric or barometrical condition which is equally essential to their life. Small-pox once remained in this city for more than two years, then it disappeared. Once we had no diphtheria here at all, till it came from California through Kentucky, Virginia and North Carolina, and was seen first in the upper counties before it travelled to Charleston. We had *membranous croup* before diphtheria. Scarcely a case (we know of but one) of the former has been seen since the war.

There is a parish (St. John's, Berkley), only forty miles from this city, to which, so far as we can learn, a case of diphtheria was never yet conveyed, if we may except an occasional case, perhaps, on its lower border on the Cooper River, which is in direct water communication with this city; and yet we have discovered that in this parish, fifteen by thirty miles in dimension, has occurred a few years since some unique and isolated examples of hemorrhagic malarial fever—a disease we have never seen or heard of elsewhere in this State.

No one has yet discovered what is that precise atmospherical condition which is necessary to the life and persistence of these infectious diseases, and which being changed or exhausted, the diseases die out. We believe, with respect to yellow fever and its mild *congener dengue*, that *ice* kills them virtually, though specimens of either disease have occasionally been with us as late as December.

Typhoid fever has certainly been a little more prevalent here than usual during the past three months, affecting persons living in fine residences near the Battery, and surrounded by comforts. This is an additional example of some atmospheric peculiarity favoring its spread, though the condition of the soil, moisture, defective drainage, infected milk, etc., may have much more to do with it than with the other diseases.

In a number of cases, five in all, we find a simple treatment, similar to that advised by Sir William Jenner, quite sufficient, namely, sponging with cold water, a fever mixture, and quinia, two grains twice a day. It is high temperature that kills, and this must be restrained, by above measures, below 103°.

NEW ORLEANS.

(From our Special Correspondent.)

PUBLIC HEALTH.—With the exception of malarial and diarrhœal affections, the city has been very healthy. The death-rate for last week was twenty-six per thousand per annum. Assuming the population to be 220,000, with 60,000 colored, the death-rate of the latter was forty per thousand per annum.

Nine cases of small-pox have been brought to the Charity Hospital for admission. One was admitted during the stage of invasion, but was sent to the small-pox hospital as soon as the eruption could be diagnosed. Nevertheless, the disease has developed itself in one of the hospital employes.

Last week, ten deaths were ascribed to malarial fever and five to dysentery. Severe malarial attacks seldom occur to persons living in populous parts of the town. It is, however, very different in the suburbs; especially,

as the situation is more remote from the river or nearer the swamps. The malarial fevers brought into the hospitals are more fatal than usual. As common in these affections, the complications occasion the increased mortality. Diarrhœa, dysentery, and pneumonia are the intercurrent diseases which bring the greatest danger to the patients. The wards of Charity Hospital are kept very nearly filled.

UNIVERSITY OF LOUISIANA.—The lectures in the medical department began November 14. The class last year numbered 220. This year it will exceed that number. It is a sad, but noteworthy fact, that since 1867, seven deaths have occurred in the medical faculty of this school.

CENTRAL NEW YORK MEDICAL ASSOCIATION.—The fourteenth semi-annual meeting of the Central New York Medical Association was held in Syracuse, November 15. The first paper read was on *Mobility of the Stomach*, by Dr. W. S. Ely, of Rochester. The doctor spoke of the difficulties encountered in diagnosticating diseases of the viscera below the diaphragm, and cited three cases, which he conscientiously referred to as "errors." In the first case he was called in consultation to confirm a diagnosis, yet was honest in his conviction, from the appearance and symptoms, and from the existence of the characteristic tumor, that the case was one of cancer of the stomach. A post-mortem examination subsequently proved the error. The stomach was very much depressed; the pylorus was two inches to the left of the umbilicus, hardened and inflamed. The swelling was produced by the gall-bladder, which was filled with gall-stones. The other two cases were equally interesting, and prove the expediency, in all cases, of making a careful examination.

After discussion of the above paper, Dr. Creveling, of Auburn, read an article on *Laryngeal Phthisis*, in which he maintained that laryngeal phthisis may be present without consumption existing elsewhere.

Dr. Ely then exhibited a hypodermic syringe revised and modified by himself, and manufactured by Tiemann, of New York. The instrument is commendable because of its compactness. The needle is inclosed in the piston, and the barrel has a close-fitting cap, which prevents the possible entrance of air or dust. The syringe is about as large as a lead-pencil.

At the afternoon session, Dr. Van De Warker, of Syracuse, read a well-written article on *The Forcible Elongation of Pelvic Adhesions.*

Dr. M. H. Brown presented a case of *symblepharon*, which was produced by the formation of cicatricial bands (scars), the result of a burn by a piece of red-hot iron. The case was peculiarly interesting from the exceptionally good result obtained from the comparatively novel operation. The first operation was performed in September. It was unsuccessful, the bands, after removal, again forming. The second operation was performed last October. It consisted essentially in removing the cicatrices from the eyeball, and so loosening the lid, cutting away the adjoining conjunctiva, and substituting a piece equal in size to that destroyed, from the conjunctiva of a rabbit. This was stitched into the wound, thereby keeping the surfaces separated, and a complete and radical cure was the result. The piece of rabbit's conjunctiva is now coursed with blood-vessels, and is as sensitive as the rest of the eye.

After a discussion on dislocation of the hip, the Society adjourned to meet in Rochester, May 17, 1882.

KENTUCKY STATE MEDICAL SOCIETY PRIZE.—The Committee on Prize Essays has offered fifty dollars for the best essay embodying the results of original experimental research or original clinical observation on the nature, mode of propagation, pathology, and treatment of scarlatina. Only members of the Society are allowed to compete. Essays must be sent in before March 15, 1882, to D. S. Reynolds, M. D., Chairman.

HONORS TO AMERICAN PHYSICIANS.—At the meeting of the Clinical Society of London, on October 14, Dr. H. J. Bigelow, of Boston, and Dr. J. S. Billings, of Washington, together with Sir James Paget, Prof. Esmarch, Prof. Volkmann, Prof. Verneuil, M. Ollier, M. Pasteur, and Drs. Pantaleoni and Mazzoni were nominated by the Council as Honorary Members of the Society, in commemoration of the meeting at London of the International Medical Congress of 1881.

SIR ERASMUS WILSON.—The Queen has conferred the order of Knighthood on Sir Erasmus Wilson, President of the Royal College of Surgeons of England, "in consideration of his munificent gifts for the support of hospitals, and the encouragement of medical study." Among his gifts to hospitals has been the erection, at his sole cost, of a wing of the Margate Infirmary, involving an outlay of $150,000. He also defrayed the expense, $50,000, of bringing Cleopatra's needle to England and setting it up on the Thames embankment, and he founded the chair of Dermatology in the Royal College of Surgeons, and endowed it with $25,000. Sir Erasmus Wilson is seventy-two years of age, and his fame as a dermatologist is world-wide.

VIRCHOW'S JUBILEE.—The greatest of the honors conferred upon Virchow, in the celebration at Berlin in commemoration of his sixtieth birthday and of the twenty-fifth year of his professorship, is the foundation of the Virchow Institute for Promoting Anthropological Studies, to be under Prof. Virchow's own direction. Seventy thousand marks were subscribed towards this project in the various European countries. The presentation was made by Prof. Bastian at a brilliant fête given at the Roth House, in Berlin, on November 22. In commemoration of the same occasion, Virchow was tendered a banquet by his former assistants, now some of the most distinguished pathologists in Germany, and a marble bust was erected in his honor in the hall of the Pathological Institute.

METHOD OF APPLYING NITRIC ACID AS A CAUSTIC.—To prevent the spreading of nitric acid when used as a caustic, Dr. Speirs recommends, in the *Practitioner*, that the part to be cauterized, as, for example, a nævus, should first be surrounded by a short glass tube or neck of a bottle, of the size of the slough desired, and then the nitric acid applied with a pipette. Before removing the tube, the excess of acid is to be mopped up with cotton-wool on a probe.

NOTES AND QUERIES.

DOUBLE FEMORAL ARTERY.

MR. HOWARD A. KELLY has observed three cases of double femoral artery, in which the femoral divided into two trunks below the origin of the profunda to reunite above the Hunterian canal. One case like that of Mr. Bell (*Anderson's Quarterly Journal, 1826*), was the subject of ligation, and to this peculiarity the man owed his loss of life. Another case was in the leg of a white man, dissected by Dr. Griffith, at the University of Pennsylvania. The third occurred in the leg of a white woman, in Jefferson College dissecting-rooms. These cases Mr. Kelly will report in detail in the January issue of the *American Journal of the Medical Sciences.*

AUTHOR OF LISTERISM.

AT the meeting of the New York Academy of Medicine on October 20, books and papers were presented which had been received from Dr. Déclat, who in them claimed priority in the advocacy of the so-called antiseptic method.

SUPRA-PUBIC LITHOTOMY.

DR. A. GROVES reports two successful cases of supra-pubic lithotomy in the *Canadian Journal of Medical Science*, for Nov., 1881.

ORIGINAL LECTURES.

CLINICAL LECTURE
ON THE TREATMENT OF CLUB-FOOT.

Delivered at Bellevue Hospital.

BY LEWIS A. SAYRE, M.D.,

PROFESSOR OF ORTHOPEDIC SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

GENTLEMEN: I fear that you will think we are never going to quit the subject of club-foot, as I have already several times had occasion to lecture to you upon this matter within the past few weeks. More cases, however, continue to present themselves for treatment, and as the deformity is one which you will be called upon to remedy more frequently than almost any other, when you begin practice, I have thought we could profitably devote another hour to its consideration.

Club-foot is of such common occurrence, and, strange to say, its treatment so little understood or practised, that I can confidently assure you, if you will but follow the instruction which I give you for its treatment, you will be able to cure a very large proportion of the cases which are brought to you, thus reflecting great credit upon yourselves as practitioners, and will rarely have occasion to send your patients to so-called specialists. Patients are constantly being sent to me for treatment from all parts of the country, from the South, East, and West, and for the simple reason that the principles of treatment of these cases are not understood. For ten years I have been trying to inculcate these principles into the minds of physicians, but they have not yet received that general adoption by the profession which I believe they merit. So soon as they do, any one of you, or any other medical man, can relieve deformities of this kind as well as I can. There is no mystery in the treatment, and nothing about it but what you can do as well as any one else; there is no specialism in it.

Talipes Equino-varus.—This young lady is seventeen years old, and presents with a very bad case of talipes equino-varus upon the right side. You will observe that the cuboid bone is subluxated so as to form a projection. With the increasing weight of the patient, the contraction of the tendo-Achillis, and the shortening of the arch of the foot by the contraction of the tibialis anticus, the deformity has been gradually getting worse, so that she now walks upon the outer border of her little toe. Walking upon the foot in this abnormal position gives the patient great pain. She states that this deformity has existed all her life. Her case is a good illustration of the importance of following the advice which I gave some years ago, namely, that the proper time to attend to deformities of this kind is immediately after the birth of the child. As soon as you have given the mother the necessary attention after the birth of the child, and before you leave the house, you should always examine the child and see if there be any deformity present. If so, you will, by thus early beginning treatment, be able, in the great majority of cases, to restore the distorted member to its normal position, so that by the time the child is old enough to walk, the foot will be in proper position to receive the weight of the body, which in itself will tend to prevent the return of the deformity.

Suppose, for instance, you find a child at birth with talipes equino-varus. Ordinarily, such cases are of paralytic origin, or there may be a spasm of the muscles producing the deformity. No matter what be the cause, the deformity is the same. If of paralytic origin, it can be replaced upon the instant without the use of much force, but will often return to the abnormal position upon letting go of it. If not of paralytic origin, considerable force will have to be expended before you can restore the foot to its normal position. The replacing of the foot is accomplished by firm but gentle manipulation with the hand crowding it towards its normal position, rotating it outward, elevating the toes and expanding the arch so as to put the plantar fascia and the tendo-Achillis upon the stretch. After doing this, you will observe that the foot becomes of a snowy whiteness, and if you were to fix it in this position, the pressure required to keep it there would be so great that it would deprive the parts pressed upon of their nutrition, and there would be sloughing. Hence, after you have held the foot in its rectified position for a few seconds, you should let go your hold of it and allow the blood to return. As soon as the circulation has been restored, you should go through the same manœuvre again, this time holding the foot in the improved position a little longer, or until it becomes whitened, and then let go of it. If the case be one of double talipes equino-varus, after you have replaced one foot and let go of it, take the other and repeat the process with that. By the time you have reduced the deformity in the second foot, the circulation in the first will have been restored, and it can be again replaced as before. This process should be repeated twenty, forty, or a hundred times, as the case may be, until you can restore the foot nearly, or quite, to its normal position without the use of much power. After you have done this, you should ascertain to what extent the deformity can be rectified without interfering with the nutrition of the foot—without the foot becoming whitened, and secure it in this position with a roller bandage. If you can completely rectify the deformity without the foot losing its normal color, it will be safe to secure it in its natural position. Unless this can be readily accomplished, however, do not try to correct the deformity at that particular sitting. The leg of an infant should be first protected with a roller bandage of flannel before applying the adhesive strip, otherwise there would be danger of excoriation of the skin. The adhesive strip is placed with one end on the dorsum of the foot, then carried to the inside, underneath, and to the outside of the foot and up the leg. Sufficient tension is put upon the adhesive strip to draw the foot into as nearly a normal position as possible, compatible with the free circulation of blood within it. It is then secured in this position with a few turns of a roller bandage. The foot should be submitted to repeated daily manipulations while the bandage is yet applied. When the bandage is removed, which should be done every one, two, or three days, as the case may be, the parts should be washed with alcohol and water, the foot restored to its normal position several times, and then retained as nearly as possible in this position with a roller bandage. After a time you can mould a piece of leather to the foot, by first making it pliable by dipping in cold water. Or a very convenient method of accomplishing this is to take one of those little wooden models of a foot and leg of about the size of that of your patient, such as are used by ladies to place inside of stockings to facilitate darning them, and mould the leather over this, securing it in position with a bandage, and allowing it to dry, after which it can be applied to the foot. You continue to rectify the deformity in this way until the child is able voluntarily to

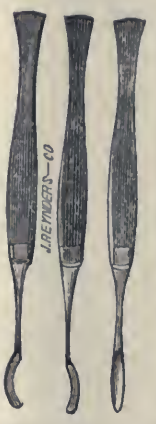
hold the foot in its normal position. As soon as the child begins to walk, the weight of its body will help to keep the foot from being displaced, and will complete the cure.

If the deformity is not corrected before the child begins to walk, pressure upon the foot in its abnormal position will intensify the deformity, and that which was at first a very slight and easily rectified abnormality becomes painful and difficult to cure. Pressure upon parts not provided with protective cushions gives rise to the formation of bursæ upon the outer margin of the foot. Further neglect may result in excoriations and sores, producing an inflammatory action, followed by reflex contraction of the muscles, which in turn, owing to their constant irritation, become structurally changed —shortened: *contractured*. When these changes have taken place, and the fibrillæ have become adherent one to another, no amount of power short of severing the diseased tissues will enable you to rectify the deformity. They must either be ruptured or divided, or, what is better, make subcutaneous section of them. Now, how are you to determine whether a muscle be contracted or contractured? To do this, bring the foot into as nearly a normal position as possible, and then apply point pressure to the part thus put upon the stretch; if reflex spasm is produced, the tendon, fascia, or muscles pressed upon are contractured, and require section in order that the deformity may be rectified.

You observe in the case of this young lady, when I put the plantar fascia upon the stretch, point pressure produces reflex spasm. The same is true of the tendo-Achillis. The inference then is, that it is useless to make any attempt to straighten this foot without first dividing the contractured tissues. As the operation is accompanied with considerable pain, it will be necessary to anæsthetize the patient. In doing this it is always essential to have the clothes loosened, so as not to interfere with the respiration. The lesson to be learned from this case is that whenever you make section of tendon, fascia, or muscle, for the relief of deformity, on that instant restore the foot to its normal position. By thus separating the ends of the divided tissue to the extent required for the correction of the deformity a space—vacuum—will be left, into which exudation will take place, and the exuded material will rapidly become organized. The old plan was to delay rectifying the deformity after the contractured tissues had been divided until the external wound had entirely closed and the inflammatory action which may follow the operation had subsided. Mechanical force was then applied and the newly-organized material exuded between the ends of the divided tissues was stretched until the foot was brought into its proper position. This stretching process was always very painful, and kept up a constant irritation, frequently resulting in inflammation and suppuration. Even after the foot was brought into its place, if the mechanical appliances were removed, it was very apt to flop back into its old position, owing to the want of power on the part of the muscles to retain it where it should be.

In regard to the knife to be used in the subcutaneous section of tissues, it is exceedingly important that it possess certain peculiarities. The handle should be so marked that you can always determine the direction of the cutting edge, though the blade be deeply buried in the tissues. The shank should be strong and well set in the handle. The blade, which should be about three-quarters of an inch in length, and either curved or straight, should be made very thick at the "back," and always rounded on the end. Most instrument-makers make their tenotomes sharp pointed, and those surgeons who use them run great risk of dividing arteries or veins, or puncturing nerves. Fig. 1 represents three varieties of tenotomes made by Messrs. Reynders & Co., of this city, for me. That which has its cutting edge upon the convexity of the blade is the one which I use almost exclusively.

FIG. 1.



I will now divide the plantar fascia, and as I do so, the part being put upon the stretch, I can hear the snapping of the fibres and plainly feel them giving way. As the knife is withdrawn, and without a drop of blood having escaped, I place a small bit of adhesive plaster over the wound, thus effectually shutting out all air. Next I will divide the tendo-Achillis. You introduce your knife flatwise and in such a manner as to make a valvular incision through the skin. The blade of the knife, still kept flatwise, is carried beneath the tendon to the opposite side, when it is turned with its cutting edge towards the tendon. The tendon is now pressed down upon the knife, while at the same time a moderate sawing motion is given to the blade until the tissues are divided. As my knife is passing through the tendon, you can hear a squeaking noise, and now, a sudden snap, indicating that the tendon is completely divided. Upon withdrawing my knife, I place a piece of adhesive plaster, as before, over the site of the incision, and then proceed, by manual pressure, to bring the foot into its normal position.

We are now ready for the application of the foot-board. The foot-board which I shall use in this case, and would recommend to you in all similar cases, is of very simple construction. It consists of a thin piece of board an inch or so longer than the foot, shaped somewhat like the sole of a shoe, but made narrow at the heel and broad at the toes. A strip of adhesive plaster, about an inch or an inch and a half wide, and long enough to pass over the instep and down underneath the board again, is placed with its middle part against the heel of the board, and a longer and broader strip of adhesive plaster, placed lengthwise of the board, beginning at the toe-end underneath, is passed back over the heel to the under side of the board and brought forward to the toe-end. The board is now padded, under the adhesive plaster, with cotton on the side which is to be placed against the sole of the foot. A firm bandage is applied over the adhesive plaster, and holds everything in place. The board is now ready for use. The malleoli and other bony prominences are protected from undue pressure by a liberal use of cotton, and the board is placed in position upon the foot. The foot is first brought to a right angle with the leg, and the two ends of the heel-strap are then brought forward, crossed over the instep, and passed to the under side of the board. It is necessary that the foot be placed at right angles to the leg before this is done, otherwise there would be danger of obstructing the circulation by making undue pressure with the adhesive strap. The foot is now securely fastened to the board by a roller bandage. The next step is to bring the broad strip of adhesive plaster attached to the toe-end of the board up against the front part of the leg, making sufficient traction upon it to retain the foot at a right angle to the leg. It is then secured with a few turns of the roller bandage, and the dressing is complete. Sometimes it is necessary to have an additional strip of adhesive plaster extending from the inside or outside of the foot to a position upon the leg, according to whether the foot is turned to the outside or inside. This dressing is much simpler than Stromeyer's foot-board, is inexpensive, and fulfils all the indications to be met. No complicated or expensive apparatus is required. The most important and most difficult part of the whole dressing

to procure is a good quality of adhesive plaster. This case was discharged at the end of six weeks from the hospital without deformity, and able to flex the foot voluntarily to more than a right angle. Was exhibited before the class December 14, 1881, before leaving the hospital.

The same principles which have been applied to this are applicable to any other form of club-foot. Of course, you will not be able to relieve all cases, but the earlier you begin treatment, the better will be your chances of effecting a cure. It is sometimes very difficult to restore the function of the muscle. Very often, if the case be left until adult life, the bones of the foot will have become so altered that it will be impossible by this means to rectify the abnormalities of bony structure. Thanks, however, to the efforts of Prof. Lister, we are now able to deal very successfully even with this class of cases. Under the antiseptic spray we can cut directly down upon the bone with perfect freedom and safety, remove a wedge-shaped piece, and restore the foot to its normal position, an operation which only a few years ago was entirely impracticable.

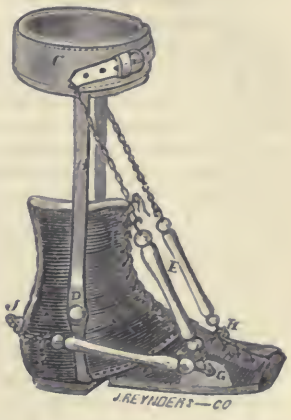
Talipes Equino-varus—Section of Plantar Fascia and Tendo-Achillis—Hudson's Shoe—Rapid Progress towards Recovery.—I merely asked this little girl to come to the clinic to-day in order that you might see how rapidly these deformities can be rectified. The deformity which existed was a perfect duplicate of that of the young lady which you have just seen. The only difference between the two cases is the age of the patients—this one being seven years old and the young lady seventeen. It lacks two days of being three weeks since I operated on this little girl. She is now able, as you see, to stand with her heel upon the floor. I operated upon her in exactly the same way as I have upon the young lady—making section of the plantar fascia and tendo-Achillis subcutaneously, and dressing the foot in the manner I have already shown you. At the time of the operation there was no loss of blood whatever. The healing of the wound was completed without the formation of a drop of pus, and after ten days she was able to make traction with her tendo-Achillis; but she could not, nor can she now, voluntarily flex her foot on account of the paralysis of the muscles on the front part of the leg. Having rectified the deformity, we have now to cure the disease, namely, the paralysis of the muscle. Do not make the mistake of thinking that when you have reduced the deformity you have cured the disease. Not until the function of the muscles has been restored to such an extent that they hold the foot in its normal position should the case be discharged as cured. To this end the muscles should have the benefit of daily massage and the application of electricity. The injection of a solution containing one-eightieth of a grain of strychnia, directly into the paralyzed muscles, is often of considerable service in restoring them to their function. This can be done by means of a hypodermic syringe, and may be repeated every ten, twenty, or thirty days, according to circumstances, until the muscles have recovered their power and the foot is held in its normal position by them without other mechanical aid. Until then no cure has been effected.

FIG. 2.

This little girl you see is wearing a shoe (see Fig. 2), to the sole of which is fastened two iron rods jointed at the ankle and running up on either side of the leg to the top of the tibia. At the upper end a padded band encircles the leg, and to this are fastened little hooks, to which, in turn, are attached India-rubber muscles, which pass downward on each side of the leg. The lower end of each of these rubber muscles is furnished with a piece of strong catgut, which plays over a semi-circular wheel opposite the ankle-joint. By this means any amount of tension can be exerted upon the foot, and it can thus be readily kept in its normal position. I used to have a shoe constructed with a stirrup over the toes, to which was attached an elastic strap, extending up to the band encircling the leg just below the knee. But Dr. Hudson has devised this shoe, which I consider a very great improvement upon mine.

Talipes Equino-varus.—Here is another case of talipes equino-varus. The deformity is apparently so slight that most persons would think that no operation would be required. I see that the girl is wearing what pretends to be one of my club-foot shoes (see Fig. 3); but, on account of its faulty construction, it is of no service whatever.

FIG. 3.



The lateral movement, so important to these cases, is entirely prevented, owing to the fact that the part of the sole adjacent to the heel has not been properly made; hence the elastic side-straps are prevented from acting. This difficulty can easily be rectified by rounding off the inner and outer corners of the sole next to the heel, so as to allow full play of the orbicular joint, opposite the medio-tarsal articulation. The shoe is of such simple construction that any intelligent blacksmith, in any part of the country, could readily make it. The late Prof. Crosby devised a very serviceable and cheap substitute for my shoe in the following manner: Taking a pair of stout shoes that fitted the patient, he cut the sole of the one for the deformed foot directly in two, at a point opposite the medio-tarsal junction; the two parts were made fast to each other by means of links of a chain, and the necessary inversions or eversions produced by elastic straps.

Upon a careful examination of this patient, I find that no shoe will do her any good until an operation is performed, because the muscles and fascia have become contractured. Now, observe what takes place when I press upon the plantar fascia, after it has been put upon the stretch. You see, there is a reflex spasm; the same is true with the tendo-Achillis. Hence, I shall proceed to operate in this case as I have done in the other.

In the course of a few weeks she will be able to put on the club-foot shoe, which she will wear with advantage. Electricity, massage, and the cold-water douche should be employed to complete a cure.

One word in regard to the application of electricity in these cases. Before applying it, the deformity should be reduced, as far as possible, by means of manipulation with the hands, so that when the muscles are caused to contract by the application of electricity, they should be placed in the most advantageous position possible. If you have no battery at hand, you can cause vigorous contraction of the muscles by taking them up between your thumb and fingers, and giving them a sharp, quick pinch. Here, in this case, you see this shows very plainly; every time I pinch the muscles of the leg, you see the foot is drawn up. Returned at end of two weeks,

when tendo-Achillis was firmly united, so that she could voluntarily extend the foot. One month later was shown to class perfectly restored and wearing ordinary shoe.

LITHOLAPAXY: WHAT IS ITS VALUE?

By W. H. VAN BUREN, M.D., LL.D.,
PROFESSOR OF SURGERY IN BELLEVUE HOSPITAL MEDICAL COLLEGE, N. Y.

WHEN a novelty in surgery claiming superior merit is promulgated under good auspices, it becomes the duty of those by whom it has been subjected to trial to make known the results of their experience.

Shortly after reading in the *American Journal of the Medical Sciences* for January, 1879, the paper of Prof. Henry J. Bigelow, M.D., of Harvard, on the operation which he has styled "litholapaxy," or lithotrity completed at one operation, I subjected a patient with stone to the new process. The favorable issue of this case led me to repeat the new operation upon the next case that offered; this was also successful; and it so happens that since that date I have had occasion to employ, or to advise, no other operation for stone in the adult.

I have been led to this course by the simple fact that the bladder has invariably shown the unexpected and entire tolerance of the prolonged operation which Prof. Bigelow was the first to demonstrate that it possesses, when properly managed.

In thirty-four cases in which I have been more or less immediately concerned since January, 1879, no stone has been encountered, although the majority were of considerable size, which could not be grasped and crushed by the lithotrite; and in no instance has there been a failure to free the bladder from stone in a reasonable time at one operation. Of these thirty-four cases in which the lithotrite has been used by myself, Dr. Keyes, or Dr. L. A. Stimson, singly or conjointly, thirty-three have resulted in reasonably prompt and satisfactory cure. In the solitary fatal case there was pre-existing suppurative inflammation of both kidneys, masked by the aggravated sufferings of the patient, and suspected, but not certainly made out. It was evidently not a fit case for this or any other operation.

In one of the latest cases, an otherwise healthy man of sixty-eight, who applied to me for bladder disease of long standing, not knowing he had stone, the unusually large amount of ten hundred and sixty-five grains of dense brown urates were removed in seventy-five minutes. There was but one stone in this man's bladder, and its grasp was over an inch and a half. The patient was up and about within a week.

In the latest case, a man of seventy-five, with quite a large prostate, four hundred and fifty-three grains of phosphate stone were removed in sixty-five minutes, and the bleeding (from the prostate) was unusually profuse; but there was no chill, and the sequelæ were favorable. In these cases the operation was done entirely by Dr. Keyes.

The cardinal feature of this operation, which explains the remarkable absence of after ill effects, is that the bladder, relieved from the presence of a foreign body in its cavity, is left at rest, and free from any cause of further irritation. In this respect it shares the great advantage of lithotomy.

In less than a third of the cases the catheter has been required for a day or two after the operation; but the subsequent atony of the bladder, which we had been led to anticipate from the experience of ordinary lithotrity, has been conspicuously absent. In fact, in no case which has passed within my cognizance, have there been any symptoms showing other than complete tolerance on the part of the bladder under gentle and judicious manipulation, and entire absence of bad effects afterwards.

In a certain proportion of the cases in which there has been chronic cystitis previous to the operation—say one in six or eight—the patients have continued to form phosphatic gravel in the bladder from time to time; but this tendency has been antagonized by systematic washing out by means of the fountain syringe.

The youngest of our patients subjected to litholapaxy was a boy of nineteen. In children I am not prepared to advise this operation, although the instruments we have employed are not larger than the ordinary lithotrites. But in view of the narrowness of the urethra before puberty, and of the fact that I have never lost a child after lithotomy in between thirty and forty cases, I should give preference to the knife.

Cases of stone will doubtless occur in which urethral stricture or rigidity may prevent the employment of large evacuating tubes so desirable in the new operation, or in which a patient's feebleness may render it necessary to cut short the proceedings before the bladder has been entirely cleared out, but these must be exceptional.

From my experience of the last three years, I judge that the operation of lithotomy, except in children, bids fair to become a somewhat rare and unusual proceeding, in the presence of a safer and equally efficient remedy.

Let us give due credit, then, to Bigelow's original improvement in the treatment of stone in the bladder, which, unless I am in error, promises to add great honor to American surgery.

No. 1 PARK AVENUE, NEW YORK.

THE PRACTICAL EXAMINATION OF RAILWAY EMPLOYÉS,

AS TO COLOR-BLINDNESS, ACUTENESS OF VISION AND HEARING.

BY WILLIAM THOMSON, M.D.,
PROFESSOR OF OPHTHALMOLOGY IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

AT the conclusion of the International Medical Congress last August, in London, but two subjects were thought so important as to be desirable to be brought before the Congress for its official sanction as the voice of the entire profession. Resolutions were adopted, 1, strongly urging the necessity of vivisection in advancing medical science and art; and, 2, strongly urging upon the various governments to appoint delegates to an international commission to

agree upon tests of sight suitable to be enforced in the case of signallers and look-out men and such, by land or sea, with a view to the safety of life and property. This resolution emanated from the Ophthalmological Section, and was drawn up by a committee consisting of the following persons, all of whom had made themselves conspicuous by their studies upon this subject, and by their labors to effect this reform by appeals to the authorities of their various nations: Chairman, Prof. Donders, for the Netherlands; Mr. Wm. Bowman, for Great Britain; Dr. Dufour, for Switzerland; Dr. Gama Lobo, for Brazil; Dr. Samuel T. Knaggs, for N. S. Wales; Prof. Leber, for Germany; Dr. Libbrecht, for Belgium; Dr. L. Maréchal, for France; Dr. Ole Bull, for Norway; Dr. Osio, for Spain; Dr. Reymond, for Italy; J. T. Rudall, F.R.C.S., for Victoria; Prof. W. Thomson, for the United States; Dr. Warlomont, for Belgium; Secretary, Dr. Brailey, London.

That no wide control has as yet been obtained is shown by the need for further action advised by the Congress; but the discussions, and an acquaintance with the schemes that had been and were then proposed, convinced me that one of the main difficulties has been found in the need of some more simple method for determining the color sense, since all those now before the profession demand the presence of special or medical experts of high culture to pronounce upon the individual applications of the test, and specialists of this type are not abundant in any country.

In the hope that a common standard for land and sea, which would give a qualitative as well as a quantitative test for color sense, might come into general use, the committee will recommend the iso-chromatic tables on the principle of Stilling, consisting of squares of confusion colors and test colors intermingled so as to form letters, but which will be found too complicated to be trusted to any but trained examiners of special educational fitness, or, in other words, medical men acquainted with the diseases and defects of the eye.

The European idea seems to be to propose to the governing powers an organization composed of medical experts in sufficient number, who shall personally examine the railway employés under the direction of some one or more eminent ophthalmic surgeons, to be paid by the government, to establish a standard for sight and color sense, and to give or withhold certificates which will entitle the men to remain in or leave the service. From the failures to secure this control it may be inferred that opposition has been successfully made by the railways, or that the persons in authority have not been convinced of the practical value of the schemes. No steps have yet been taken in England, and it is felt that there, as in this country, no amount of agitation would suffice to bring the railways under such legislation.

Upon the conclusion of the labors of the committee, the plan described below was briefly mentioned as the one most feasible in our country, and much interest was shown in it, and in the instrument for the use of the detection of color defects; and it was agreed that with it any properly instructed non-medical person could make the first examinations, and transmit the results for the decisions of a medical authority; and that large bodies of men might thus be safely passed through the testing without the presence of medical examiners. One member of the committee has already sent to me for the instrument, with the statement that he will advise his government to employ it on the railways; and another instrument has been sent through the British Consul at Philadelphia, at the request of the Secretary of the Marine Department, for the use of the Board of Trade in London.

In giving, then, the details of the system for examination into the "sight, color sense, and hearing," which was prepared by me for the Pennsylvania Railroad, and perfected by the aid of a committee of their transportation officers, and which has been adopted, I feel that a decided step forward has been made, and that the ideas which underlie it are substantial, viz., 1. That it would be impossible by any agitation to subject a road passing through many sovereign States to legislation which might be considered hostile to its interest. 2. That for the protection of lives and property any road would gladly accept the aid of scientific advisers when offered in a practical form.

The signal failure to carry out State legislation obtained by public agitation in Connecticut, under which scientific experts, designated by the Governor, and paid by the road, were provided for; and fixing severe penalties for the employment of any man not provided with experts' certificates, proved that the officers of the roads were not willing to submit their employés to the scrutiny of State officials who, adopting their own standards, could practically summarily discharge perhaps fifteen per cent. of their men, disturb the discipline and impair the organization of their roads; whilst the political power of a large number of such employés, each with a ballot, was fully demonstrated in their successful demand for the repeal of this law. Any advice on this subject to be accepted by the railway officials ought to be given by scientists of their own selection, and must be confidential, in order that they may either discharge men unfit for service, or transfer to positions where they can do no harm those who by education are too valuable to be lost to their service; whilst the men would gladly accept any wise precautions against the dangers of their occupation which could be provided for their own safety.

These difficulties are overcome by the employment of the instructions which I have prepared for the use of the Pennsylvania Railroad, and which can be followed by a non-medical person, properly instructed, who will place the results on a blank, and transmit them to the professional expert having supervision of the entire examination. From these data a just decision can be made as to the sight, color sense, and hearing of each employé.

In accordance with a wish expressed many months ago, that I should suggest some practical method for the examination of the employés of the Pennsylvania Railroad, as to their ability to see the colored signals by day and night used in the service, I de-

voted much time to the subject, in an effort to overcome the following difficulties:

1. To ascertain whether each man possesses *sight* enough to see *form* at the average distance; and *range of vision* to enable him to see near objects well enough to read written or printed orders and instructions. 2. To learn if each man has color sense sufficient to judge promptly, by day or night, between the colors in use for signals. 3. To determine the ability of each man to hear distinctly.

The difficulties to be overcome were found in the magnitude of the task, involving the examination of thirty-five thousand men now in the service, with the necessity of extending it to all who may be hereafter employed, distributed over thousands of miles of road; and in the absence of professional experts in sufficient number, possessing enough special training to fit them to decide with precision the points in issue.

It soon became apparent that some system would be needed that could be put in force by each Division Superintendent, acting through an intelligent employé, under the general supervision of one or more ophthalmic surgeons of recognized skill, to whom all information collected could be transmitted, and who would be able to decide all doubtful cases, and thus protect the road from any danger arising from incapable employés, and save good and faithful men from the evil of being discharged from the company's service, or prevented from being employed on other roads, on insufficient grounds.

It was believed that the facts could be collected by non-professional persons, and could be so clearly presented to the Division Superintendent and to the professional expert, as to enable a perfectly correct decision to be made in every case; and that men fit for service would be recognized, whilst those deficient in sight, color sense, or hearing, could be referred to the expert if they so desired, or transferred to places in the service where their defects, if not remediable by treatment, could do no harm either to the road or to the public.

Such a system was submitted to the General Manager of the Pennsylvania Railroad some months ago, and has been perfected by the labors of a special committee of the Society of Transportation Officers in conjunction with the writer. The entire method has furthermore been submitted to a practical experimental test extending over nearly two thousand men, employed as conductors, engineers, firemen, and brakemen, and the results have satisfied the committee and myself that our object has been fully attained, and that the system proposed may now be put in force with confidence in its practical utility. As an evidence of this, I may cite two complete detailed reports, including 1383 men in all. The blanks upon which the original entries were made, have all been submitted to me, and they satisfy me that the results in the summary of each of these excellent reports may be confidently accepted, and thus we have become acquainted with the fact that there were in the service of the Pennsylvania Railroad, of the 1383 men examined, 246 men deficient in the full acuteness of vision, 55 absolutely color-blind, and 21 defective in hearing.

In one of the reports, an examination not included in the instructions from the committee, was made with colored flags and colored lights by night, and 13 men failed to be able to recognize them from a total of 24, who were color-blind to the test used for its detection, but I have little doubt whatever that the entire number of color-blind, viz., 55, would also fail under a carefully-devised system of tests by the usual railroad signals.

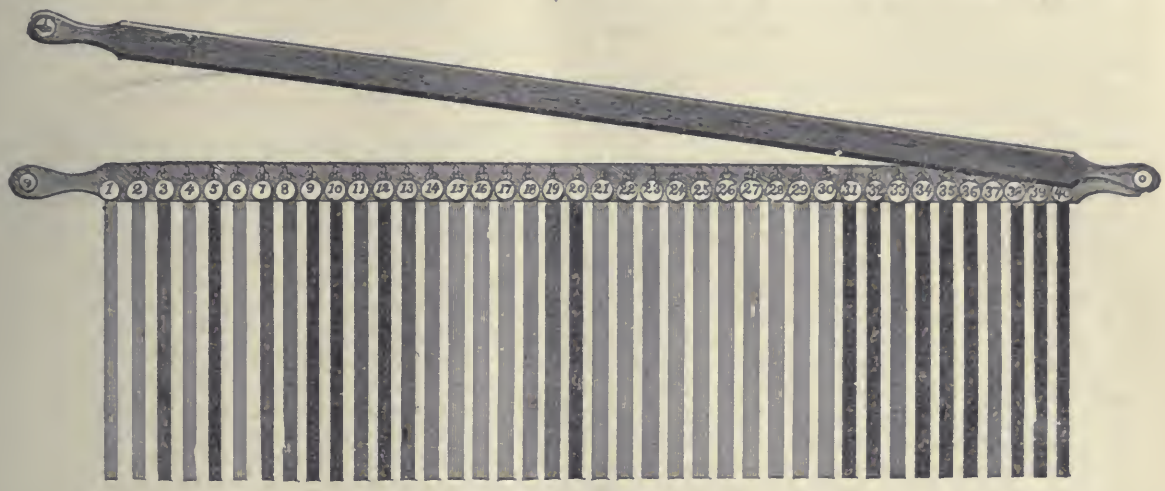
The entire number reported as *defective* in color sense, $4\frac{2}{10}$ per cent., is up to the average, as reported by the best authorities in its percentage; but those absolutely color-blind, and hence unable to distinguish between a soiled white or gray and green, or a green and red flag, are fully 4 per cent.; and this proves that the instrument employed in this part of the examination has met our expectations fully.

As this was the point about which I had most doubt, a word or two of explanation may be proper, more especially as many great authorities declare that no examination for color-blindness should be accepted, unless made by professional specialists.

The examination for color-blindness now generally accepted and proposed by Prof. Holmgren, consists in testing the power of a person to match various colors, which are most conveniently used in the form of colored yarns. Usually about 150 tints are employed, in a confused mixture, and three test colors, viz., *light green*, *rose* or *purple*, and *red*, are placed in the foregoing order before the person examined, who is directed to select similar colors from the mass. The examiner sits then in judgment, and decides whether the color sense is perfect from the selections made, or from those *not* made, or from them both, and from the prompt or hesitating manner of the examined. It has been our effort to render this more simple, and to so arrange the colors that they may be identified by some number, so that an expert, although absent from the scene, would know by these numbers the exact tints selected, and thus be fully competent to declare from them the color perception of any person whose record had been properly made. From theory based upon scientific knowledge, and from much experience, I was able to arrange an instrument that would have the real colors, and those usually confounded with them, "confusion colors," placed in such relations to each other, and so designated by numbers, as to make an examination for color-blindness possible by a non-professional person, who could conduct the testing, record it properly, and transmit it to an expert capable of deciding upon the written results. Hence there is no departure from the system of matching tints already established, the only novelty being in reducing the number of colors to those similar to the test colors, and to those usually chosen by color-blind persons, and so identifying them as to enable an absent expert or superintendent to know precisely what colors had been selected to match the test colors.

The theory of the instrument (consisting of a stick with the yarns attached, see Figure), is that color-blindness is most promptly detected by using the *light-green test-skein*, and asking that it be matched in color from the yarns on the stick, which are arranged

to be alternately green and confusion colors, and are numbered from one to twenty, the person being directed to select ten tints, and the examiner being required to note the numbers of the tints chosen. It will be seen that the odd numbers are the green, and the even ones the confusion colors, and, that if a person has a good color sense, his record will exhibit none but odd numbers; whilst, if he is color-blind, the mingling of even numbers betrays his defect at a glance to the supervising expert or superintendent.



There are forty tints on the stick, and the first twenty are given to the detection of color-blindness, using the *test-green*, and if the color sense is deficient, it will surely be revealed.

To distinguish, however, between green-blindness and red-blindness, the *rose-test* is used, and those color-blind will select indifferently, either the blues intermingled with the rose, between figures 20 and 30, or perhaps the blue-green or grays from 1 to 20, and thus reveal their defect, and establish either green- or red-blindness.

Finally, the *red-test* corroborates these results, and satisfies the most sceptical of color defect, when the "confusion tints" or even numbers between 30 and 40 are selected.

On a suitable blank these figures are placed in the order of examination, and a glance of the eye reveals the color sense of the person examined; since, if anything but odd numbers are chosen, there is a defect; or if, with test one, anything beyond 20 is chosen; or if, with test two, anything but odd numbers between 20 and 30; or, with test three, anything but odd numbers between 30 and 40. The colors can readily be changed in the instrument, if it should be found desirable.

It is theoretically and practically a fact, that the tints as arranged on the instrument look quite the same in color to color-blind persons, and that those having a perfect color sense can thus form an idea of this infirmity. If, then, green and gray are indistinguishable, and green and red, when of the same depth of color, seem to be entirely the same to the color-blind, it needs no opinion from a scientific expert to convince the manager of a railroad that it would be most dangerous to place the lives of people under the guidance of an engineer who could not distinguish, if green-blind, between a soiled white and a green flag, or between a green and red flag, or other signal of these colors.

It is a fact that some of the color-blind promptly give the proper names to the flags, and answer correctly, when asked, what they would do in presence of such signals but it must be remembered that they may see perfectly, and have always had some perception of these colors, and do give them their conventional names, perhaps, but that they are unable to distinguish them at once and infallibly, and that it will only require a further extension of our method of testing to demonstrate the inability of persons color-blind to our examination to recognize the signals, by day or night, which are now depended upon to prevent accidents of the gravest character. This must be done by demanding that the signals be matched, and not named, and is incorporated in the instructions herewith submitted, so that the tints which color-blind men select with the railroad signals, may hereafter be known and recorded.

My conclusions from a study of the subject in connection with the railway service are:

1. That there are many employés who have defective sight, caused either by optical defects, which are, perhaps, congenital, and which might be corrected with proper glasses, or due to the results of injuries or diseases of the eyes, remediable or not, by medical or surgical treatment.

2. That one man in twenty-five will be found color-blind to a degree to render him unfit for service where prompt recognition of signals is needed, inasmuch as color-blindness for red and green renders signals of these colors indistinguishable. It is a fact in physiological optics, however, that yellow and blue are seen by those color-blind for red and green, and that yellow-violet blindness is so rare that it might lead to the use of these yellow and blue colors, in preference to red and green, wherever possible.

3. That color-blindness, although mainly con-

genital and incurable, is sometimes caused by disease or injury, and that precautions might be needed to have either periodical examinations or to insist upon it in cases where men have suffered from severe illness or injury, or when they have been addicted to the abuse of tobacco or alcohol.

4. That the method, when adopted, will enable the authorities to know exactly how many of their employés are "satisfactory in every particular" as to sight and hearing; and that the examination will have the further value of making the division superintendents acquainted with the general aptitude of the men in their divisions as to general intelligence.

5. That the entire examinations can be made at the rate of at least six men an hour; whilst that for color sense alone can be done in a very few minutes for each man by an intelligent employé.

6. That to secure the confidence of the employés, and of competent scientific critics, as well as of the public generally, it is advisable to have some official professional specialist to whom all doubtful questions could be referred, and who should be held responsible for the accuracy of the instruments, test cards, etc., to be put in use, and who should have general supervision of the entire subject of sight, color sense, and hearing.

7. That from the impossibility of subjecting the immense number of employés on our large railways to the inspection of the few medical experts available, and to secure the examination of those hereafter to be employed, some system of testing by the railway superintendents has become a necessity, and it is believed that the one prepared will answer the purpose.

By request, these views were communicated to the proper officials of the Pennsylvania Railroad Company, and on July 1, 1881, I received a communication from the General Manager, from which I make the following extract:

"DEAR SIR: I beg leave to inform you that the apparatus invented by you, and the rules and regulations entitled 'Instructions for examinations as to vision, color sense, and hearing,' prepared by a committee of transportation officers of the Pennsylvania Railroad and yourself, for the use of our officers in examining employés for defects of sight and hearing, were laid before the Board of Directors, who approved and adopted them, and authorized me to put them into effect, subject to such changes from time to time as experience may prove to be necessary for the proper working of the system.

"In putting these rules into effect, I take pleasure in designating you as the expert to whom, under the rules, such cases shall be referred as may require the judgment of an expert."[1]

A CONTRIBUTION IN REFERENCE TO THE TREATMENT OF COMPOUND FRACTURES OF THE LEG.[2]

BY ERSKINE MASON, M.D.

HAVING been interested lately to arrive at a knowledge of the usual period of time required for the repair of a compound fracture of one or both bones of the leg, as well as the method employed which seems best to answer the indications of treatment, as well as add to the comfort of patients in the majority of cases that pass under our observation, I was led to study the result of my own experience with these cases.

I find, that though a large number of these cases have passed under my observation, I am only able at present to gather complete notes of thirty cases from the time of accident to the period of their discharge. These cases have been selected from hospital practice, and represent all the varieties and various features, both as to constitution of patient and character and cause of accident, that the surgeon meets with in his ordinary hospital service. From my recollection of other cases that have been either entirely or partially under my observation and treatment, the results are about the same as those obtained from the analyses of the thirty cases.

I think I have made use of almost every kind of splint and variety of dressing in the treatment of these cases, and I have come to the conclusion that the plaster-of-Paris dressing in some one of its varieties, but chiefly the plaster bandage, with or without brackets, meets the indications in the majority of cases, either applied at once or later on in the case, better than any other appliance I have resorted to. I am well aware of the dangers which may arise in its use, but to those who are accustomed to its application, and with the requisite care and watchfulness that these cases require, I think the risks are slight and may be avoided.

The objections that some have raised as to the want of cleanliness, from the discharges flowing beneath the bandage, I believe are preventable, and when suitably bracketed, may be adapted to almost every case.

Where from various causes it would not be advisable to use the permanent dressing at once, in my hands no apparatus has seemed to give more comfort to the patient than the fracture-box, with the limb surrounded by bran, as first used, I believe, by Barton.

Though much that has been said in favor of plaster dressings may be applicable to other permanent dressings; still, the ease with which the plaster bandage is applied and fenestra cut in it, causes me to give it the preference, as well as the ease in this dressing with which the antiseptic treatment may be employed.

Some months ago a plan was adopted by some of our hospital surgeons of wrapping the leg up in large quantities of either carbolized or salicylized jute in addition to the ordinary Lister dressings, but without any other support to the limb. Though these dressings were to be removed as seldom as possible, still the changes in some had to be made frequently, at least for the first week or ten days of treatment. I have not only had the opportunity of observing this practice in the patients of others, but have given it a trial myself in several cases. It has been abandoned by me, however, for the following reasons:

The bones are not given that steady support which I believe they require.

[1] The official instructions will be found under the head of "Notes and Queries," p 59.

[2] Read before the New York Surgical Society, Nov. 22, 1881.

Each dressing entails unnecessary pain, no matter how carefully the limb is handled.

The wounded limb is kept at times too long from observation, and burrowing of pus quite extensively has taken place before it was detected.

At times so extensively bathed in pus have I noticed the limb, that though it be aseptic, I cannot but think it is prejudicial. This dressing gives to the limb too much of the appearance of being enveloped in a large poultice; if, indeed, it does not act as such.

Finally, by the bones not being firmly supported, there is more or less motion between the fragments taking place during the changing of the dressings and various movements of the patient. This I have seen cause secondary hæmorrhage, and in one case I am cognizant of, I fear was the cause of hæmorrhage which proved fatal.

With reference to the plan of treating these cases by through-drainage, as lately described by Dr. Markoe, I possess full notes of but four cases, though I have used it in other cases whose complete histories I regret I do not possess. In all these cases, I used it in connection with the plaster splint. From the results it has furnished in my hands, it has become a favorite mode of treatment with me.

Within the past few months, two cases have been more or less under my observation where the old practice of sealing the wound was employed. The sealing, however, was done by means of protective and Lister's dressing employed, and the limb firmly bandaged. In one case the bandage used was of rubber. The limbs were then securely fixed in a fracture-box. Both tibia and fibula were broken in each case. The ages of the patients were forty-five and thirty-three years. In one case the fracture was caused by a heavy piece of timber falling upon the limb; in this instance there was a great deal of subcutaneous laceration, and there were two openings leading to the fractured bones, situated about three inches above the inner malleolus. The wound was dressed August 29, soon after the receipt of fracture. September 2 the elastic bandage was removed, and considerable pus found beneath the dressings, with two or three blebs on either side of the ankle. The limb being washed with a solution of carbolic acid, the same kind of dressings was applied, save the rubber bandage. September 16, Lister dressing was removed; wounds found closed; limb allowed to remain in the fracture-box until October 6, when it was placed in plaster, and the patient permitted to go about. With respect to his temperature, it was 100° on the evening of the first day; on the evening of the second day it was 101°; after that it was normal throughout the treatment of the case.

In the other case, the fracture was produced by the kick of a horse. There were two wounds about two inches above the external malleolus, the laceration of soft parts was less than in the previous case. The case came under treatment shortly after receipt of injury, on August 27. But one dressing (Lister) was used; this being removed September 15, and the wound found closed. October 4 a plaster splint was applied, and patient allowed to move about. In this instance there was no rise of temperature.

I have met with the same gratifying result from this treatment in two cases of fracture of the femur occurring in boys, and in one case of both bones of the fore-arm in an adult, but in these cases the injury to the soft parts was but slight. I merely allude to these cases, however, as I propose to confine my remarks to fractures of the leg.

The two cases whose histories I have given were certainly such as I of late have been accustomed to treat with drainage-tubes introduced at the first dressing; and I watched their progress with much interest. They certainly have gone far to confirm what my observations have for some time been leading me to entertain, namely, that at present we are apt to be too free in the use of the drainage-tube in these cases, at least we resort to them too freely in many cases immediately upon the receipt of injury. We introduce them to anticipate the burrowing of pus, and to remove as expeditiously as possible the discharge we expect to take place. Whereas the presence of these very tubes, when too freely used, I feel sure, at times have by their presence in the soft parts invited the secretion of pus, and kept up the discharge which we desire to avoid. Certainly, I have seen two and three tubes introduced at once where I feel certain that one for the present would suffice; if indications for more arise they may be introduced later without detriment to the case.

We never can be sure if the discharge will burrow, nor the direction it will take; hence, I think at first we should be moderate in the use of the tubes.

One other point with reference to drainage-tubes. I fear that in many instances we allow them to remain too long, and, acting as foreign bodies (which they are), tend to keep up a discharge, and delay the conversion of a compound into a simple fracture. Again, when left in a long time, their tracks through the soft parts acquire callous walls, which sinuses after the removal of the tubes are long in closing.

Experience has taught us all, I believe, that since the introduction of antiseptic measures we are now enabled to save limbs that before would have been condemned to amputation. Observation, however, has shown me that we may have too implicit faith at times in the efficacy of antiseptics, and that we may attempt to save limbs which more judicious judgment, as results have proved, should have been condemned, or save limbs which are of no service to the patient, and subsequently have to be removed.

Of the thirty cases of compound fracture of the bones of the leg, we find sixteen of the tibia, three of the fibula, while of both tibia and fibula there are eleven. Seven of these cases required amputation. Of primary amputations there were five, three of which recovered, while two died—one from delirium tremens, the other from erysipelas and alcoholism. Of secondary amputation there were two cases. Both recovered.

Eighteen of these cases were treated in plaster-of-Paris dressings—either by the bandage alone or else strengthened and assisted by brackets, as the cases seemed to require. Nine of these cases were put up in the permanent dressings at once, and nine

after the lapse of some days after the injury, the average being about the twenty-fourth day.

In those cases where the apparatus was applied immediately, the average day of its removal was the twenty-fourth; while in those cases where there was necessary delay before plaster could be used, the average period of removal was the thirty-eighth day.

In those cases where the splint was applied after the lapse of some days, we find, in several instances, it had to be removed and reapplied. The causes for which we find to be in one case the splint being too loose, one from pain, one from ulceration, one from unpleasant odor arising from the splint, one from erysipelas, and one from no union.

Among these eighteen cases we find four deaths.

One from pyæmia on the eighth day. This fracture was caused by a heavy weight falling upon the upper third of the leg. Hæmorrhage was severe, and only arrested by compresses of cotton with persulphate of iron. Pulsation in both tibials was felt at the foot. Gangrene set in on the fifth day, rapidly extending, so as to involve the whole thigh.

One from shock and repeated hæmorrhages, traumatic delirium. Died on the fourth day.

One from alcoholism. Death on the seventh day.

One from erysipelas. Death on the sixty-first day.

The length of time that these patients were under treatment, viz., from the time of their accident to the day of their discharge, we find the average to be eighty-two days.

Four cases were treated by the method known as through-drainage (Markoe), viz., plaster bandage, drainage-tubes, and frequent washings with carbolic acid. The average duration of these cases was forty-nine days. Several other cases I have treated by the same method, and my impression is that they have all done well. Not possessing full notes of them, they are omitted in this table.

Five cases were treated upon Volkmann's posterior tin splint, with jute and strict Lister dressings. We find in these the average number of days of treatment to be sixty.

Among these five cases are recorded two deaths. One from pleurisy, pneumonia, septicæmia on the eighth day. The other of erysipelas upon the seventy-eighth day. This case, however, was not treated throughout upon Volkmann's splint. Union being delayed, this splint was changed to one of plaster. On the sixty-third day some sequestra were removed, splint reapplied, and erysipelas set in on the seventy-third day. In several of these cases fragments of bone were removed at various times.

In a large proportion of all these cases antiseptic treatment has been employed.

HOSPITAL NOTES.

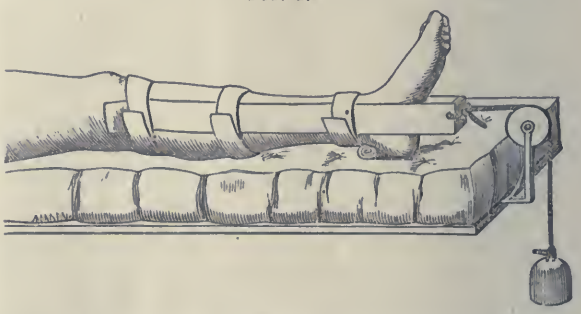
TREATMENT OF FRACTURES OF THE FEMUR IN THE HOSPITALS OF PHILADELPHIA.

(Reported by H. R. WHARTON, M. D.,
SURGEON TO THE CHILDREN'S HOSPITAL, PHILADELPHIA.)

IN the treatment of fractures of the femur, in the hospitals of Philadelphia, the most widely employed dressing is one which combines the principles of extension and counter-extension with lateral support. This dressing, from the ease with which the materials for its construction are obtained, from the simplicity of its application, and from the excellent results following its use, has become most popular with the surgeons of Philadelphia.

The dressing is applied as follows: The patient is placed in a firm bed, and the injured limb is kept moderately extended. A strip of adhesive plaster two and a half to three inches in width is then cut; it should be long enough to extend from just below the seat of fracture on one side of the limb, to a short distance below the sole of the foot, and then up to a corresponding point on the opposite side of the limb. In the middle of this strip a block of wood, perforated in the centre, two and a half inches in width by three and a half inches in length, is placed; another strip, of equal width and long enough to extend slightly above

FIG. 1.*



the malleoli on either side, is fastened to the inner side of the block, which may be held in position by several circular strips of adhesive plaster, forming a stirrup extending three or four inches below the sole of the foot. The block serves to spread the plaster and keep it from pressing on the malleoli, and also to furnish a point of attachment for the cord, to which the extending-weight is fastened. (See Fig. 1.)

The limb should be shaved if the growth of hair is abundant; the plaster is now warmed and applied to either side of the limb, circular strips of adhesive plaster two inches in width being then carried around the limb to fix the lateral straps; these strips are applied just above the malleoli, at the middle of the leg, just below the knee; and one a short distance above the knee. A roller bandage is next applied to the limb from the toes to the groin, and may be finished with a few spica-of-the-groin turns. This bandage gives fixation to the extension apparatus, and also, by its pressure, serves to control muscular spasm in the injured limb.

Lateral support is now given to the limb by two sand-bags, the outer or long sand-bag extending from the axilla to the external malleolus, the inner or short bag from the perineum to the internal malleolus. These bags are made of stout muslin, and when filled with dry sand should measure at least four inches in diameter.

A cord is then passed through the perforation in the block and fastened, and the free end is passed over a pulley attached to the foot of the bed. A weight of from five to twelve pounds is fastened to the cord, and the foot of the bed is slightly elevated to prevent the patient from sliding downwards. The weight of the patient's body in this dressing acts as the counter-extending force.

The dressing is usually kept on from four to six weeks; and when union is firm, it is removed and a plaster-of-Paris or binder's-board splint is applied to

* Represents the extending strips carried only to the knee.

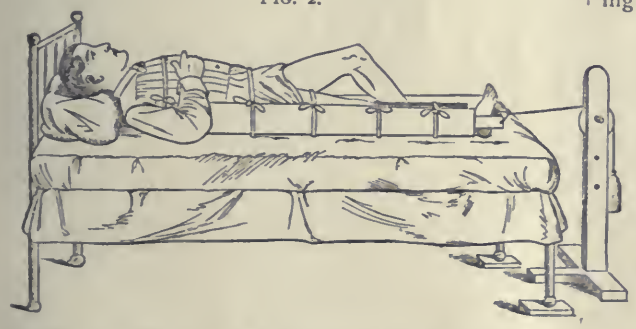
the thigh; and at the end of eight weeks the patient is allowed to leave his bed and go about on crutches. This is the dressing generally applied for fracture of the shaft and neck of the femur in the Pennsylvania, Episcopal, University, Jefferson College, Presbyterian, Children's, Philadelphia, St. Joseph's, Jewish, German, St. Mary's, and Germantown Hospitals.

Some modifications of the above dressing, though not affecting its general principles, are made by a number of the surgeons connected with the previously-named institutions.

Dr. Morton, at the Pennsylvania Hospital, uses an apparatus devised by himself for making extension. It consists of a soft leather splint surrounding and buckled to the limb a few inches below and above the knee, with an opening left for the patella; strips extend from the lower portion of this splint, and are fastened to a block below the sole of the foot, to which the extending-weight is attached; a band encircles the limb a short distance above the malleoli, which keeps the extension-strips in place.

Prof. Ashhurst, at the University Hospital, in cases of fracture of the shaft of the femur, uses the adhesive-plaster apparatus for making extension, but carries the extending-bands and surrounding bandage only to the knee, and makes lateral support by two wooden splints and bran-bags; the external or long splint extends from the axilla to the external malleolus, and the inner or short splint extends from the perineum to the internal malleolus; a splint-cloth is placed under the limb, in which the splints are wrapped; bran bags, corresponding in length to the splints, being then

FIG. 2.



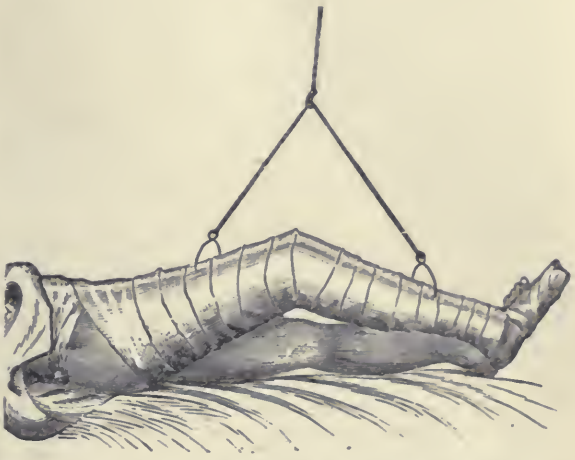
placed on either side of the limb, and the splints being brought up into position and secured by five or six bands. (See Fig. 2.) For fractures of the neck of the femur, he employs the ordinary sand-bags to give lateral support to the thigh.

Dr. Nancrede, at the Episcopal Hospital, also uses lateral splints, but carries the adhesive plaster beyond the knee to a point just short of the seat of fracture. Dr. Packard, at the Episcopal Hospital, in cases where extension does not overcome the deformity, applies over the seat of fracture, in addition to the usual dressing, short anterior and posterior splints of binder's-board, moulded to the thigh and held in place by a bandage.

Dr. Brinton, at St. Joseph's Hospital, in similar cases, uses binder's-board, or short wooden lateral splints, well padded and applied to the thigh, in addition to the ordinary dressing.

Prof. Agnew, at the Pennsylvania and University Hospitals, in fractures of the upper third of the femur, where there is an upward and inward projection of the lower end of the upper fragment, uses the anterior wire splint of the late Prof. N. R. Smith, of Baltimore. In applying this splint the limb is extended, and a spiral reversed bandage applied from the toes to the groin, the splint being then applied to the anterior surface of the limb, and fastened to it by means of a second bandage; the limb is then suspended from a frame, fixed over the bed, by a cord attached to the splint. (See Fig. 3.)

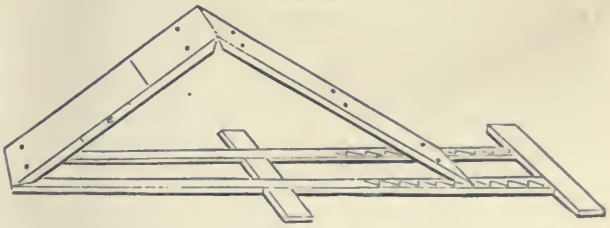
FIG. 3.



In some cases, Prof. Agnew uses the double-inclined plane (see Fig. 4) in the treatment of this fracture. The limb is placed upon the inclined plane, which has been previously well padded; extension is made by broad strips of adhesive plaster fastened to the sides of the thigh and secured by a few circular straps; the extending strips reach from a point just short of the seat of fracture to the knee, and terminate in a stirrup as in the ordinary extension apparatus; a cord is attached to this stirrup, which runs over an elevated pulley, and to this cord the weight is attached. Lateral support is given by short sand-bags placed against the thigh, or by bran-bags held in position by the sides of the inclined plane, on which the thigh rests. These may be hinged like the sides of the ordinary fracture-box.

The treatment of fractures of the femur in children presents some variety of dressing, depending upon the age of the patient. At the Children's Hospital, these fractures in very young children are treated as follows: The limb is extended, and the

FIG. 4.



fragments adjusted as well as possible; a bandage is then applied from the toes to the groin, a piece of binder's-board, long enough to extend from the foot to the brim of the pelvis, and wide enough to encircle the limb and part of the pelvis, is moistened in warm water, padded and moulded to the limb, and held in position by a bandage. This splint, when it becomes dry, holds the parts firmly in position, and permits of the child being lifted to take the breast if necessary.

In older children, the ordinary extension apparatus is applied, and lateral support is given by splints and bran-bags, or by sand-bags, the extending-weight, of course, being proportionally less than that required in the treatment of fractures in adults. In some other hos-

pitals, a flannel bandage is applied to the limb, and a plaster-of-Paris bandage carried up the limb from the toes to the groin, and finished with some turns about the pelvis, so as to fix the hip-joint.

Prof. Agnew, in treating these fractures in children, first etherizes the patient, and extends the limb, then applies a flannel bandage from the toes to the groin, and finishes it with some turns about the pelvis; a long wooden splint, extending from the axilla to the foot, is well padded and applied to the outer side of the limb, and secured to it by a plaster-of-Paris bandage, which is applied from the foot to the groin, and finished with some turns about the pelvis; the upper portion of the splint is fastened to the body by a few turns of a muslin bandage.

Fractures of the condyles of the femur are by most Philadelphia surgeons treated by extension and lateral support by means of sand-bags, the fragment or fragments being fixed by adhesive straps or compresses; or they are treated by placing the limb in a long fracture-box, extending from the foot to the upper part of the thigh, a soft pillow being first placed in the box, and after the limb is laid on this, the sides of the box being brought up and fastened by several strips of bandage, while the fragments are fixed by adhesive straps or compresses.

The application of the plaster-of-Paris bandage as a primary dressing, in the treatment of fractures of the femur in adults, has met with but little favor in the hospitals of Philadelphia.

MEDICAL PROGRESS.

TREATMENT OF SMALL-POX BY SALICYLATE OF SODA.—In the *Bulletin Générale de Thérapeutique* for Nov. 30, 1881, M. DUJARDIN-BEAUMETZ reports three cases of variola in which he obtained the most satisfactory results with the external application of salicylate of soda. In one case of severe confluent small-pox, accompanied by delirium, an ointment of cold-cream, one hundred parts to four parts of salicylate, was rubbed over the parts of the face and body where the eruption was severest; in addition to the ointment, a powder of one hundred parts of talc to six parts of salicylate of soda was dusted over the affected parts. The next day it was found that there was no increase in the size of the pustules, in some suppuration was prevented, and there was not the slightest odor developed. The data are as yet insufficient for any conclusion to be drawn as to the value of this remedy in variola, but its apparent success in the cases reported, particularly its power of destroying the repulsive odor accompanying severe cases, and its harmlessness, should lead others to repeat Dr. Dujardin-Beaumetz's experiments.

FORCED FEEDING IN PHTHISIS.—Dr. DUJARDIN-BEAUMETZ in the *Bulletin Générale de Thérapeutique* for November 15, 1881, calls attention to the method of forced feeding practised by Dr. Debove. The patients are fed through a stomach-tube, large quantities of milk, raw meat, fresh eggs, and cod-liver oil, twice a day. Sometimes the stomach is prepared by a preliminary washing, in cases treated at San Antoine by Dr. Dujardin, where symptoms of gastric catarrh are pronounced. Dr. Debove does not practise this washing, but introduces the aliment without any preparation. Dr. Dujardin-Beaumetz's mixture consists of 150 grammes (about 5 ounces) of raw meat, 4 eggs, 1 litre (somewhat more than 2 pints of milk), and he sometimes adds a little salt, cod-liver oil or peptones, the last two when there is no diarrhœa, and when diarrhœa is present he adds subnitrate of bismuth. It is very remarkable that patients fed in this way are very rarely made sick by the presence of so much material, and, as a rule, digest it with facility. If the stomach has been irritable before, and food has been rejected in the paroxysms of coughing, this no longer occurs, and the nutrition greatly improves. The general condition is also ameliorated. The pulse becomes firmer and less frequent, the cough lessens and the sweats cease. Thus far no change in the pulmonary lesions has taken place, but if such a decided improvement in the nutritive energies persists, the local morbid process, we think, cannot fail to grow better.

This method of treatment is equally applicable to tubercular lesions of the larynx or fauces where deglutition is painful or impossible.

INJECTIONS OF ERGOTINE BEFORE PERFORMING IREDECTOMY.—Dr. CH. ABADIE recommends the injection of ergotine before performing the operation of iredectomy or sclerotomy. He believes that by this means the danger of intra-ocular hæmorrhage is avoided.—*Bull. Gén. de Thérapeutique*, Nov. 15, 1881.

SIMPLE METHOD FOR THE CURE OF OZÆNA.—Dr. GOTTESTEIN (*Gazz. Med. di Roma*) considers ozæna as a constant symptom of chronic coryza. There is no doubt that, after the interference with the function of the glands, there is a diminution and alteration of the nasal secretion. Part of it, drying rapidly, adheres to the mucous membrane, on which it forms crusts, and it is the decomposition of these which is the cause of the odor. It is, therefore, only necessary that a limited portion of the mucous membrane should undergo atrophy to give origin to an ozæna. In adopting this theory of ozæna, it is evident that there can be no question of radical cure, since it cannot be hoped that the secretion of an atrophied mucous membrane can ever become normally re-established. We must therefore be satisfied with the treatment of symptoms which is the most simple and convenient for the patient.

The author was led by chance to employ the following method, from which he has already, in fifteen cases of ozæna, seen the best results in less than three months.

Dr. Gottestein commences the treatment with a nasal douche, which, by freeing the cavity from its secretions, permits the recognition of the character of the mucous membrane and the extent of the lesion. This is followed by the introduction of a tampon of cotton, 3–5 centimeters long, which should remain in position for twenty-four hours.

About an hour and a half after the introduction of the cotton, there is a little secretion from the nose. When the tampon is withdrawn, the secretion is found to be fluid and without crust or odor. Twenty-four hours can be allowed to elapse between two applications of the tampon. When both sides of the nose are affected, the nose can be tamponed every twenty-four hours on the alternate sides. The tampons cause an artificial contraction of the cavities, and so increase the action of the column of air and facilitate the expulsion of the secretions, which are absorbed as rapidly as they are formed, and their desiccation is thereby prevented.—*L'Union Méd.*, Nov. 27, 1881.

THE VAGUS AND THE EAR.—In a series of experiments as yet unpublished, which have been made by M. WIETT on the effects of stretching the pneumogastric nerve in rabbits, the effects on the ear were studied by M. Gellé. He found lesions in all respects similar to those which are produced by laceration of the medulla or irritation of the fifth nerve, hæmorrhages and

suppuration, with destruction or ulceration of the tissues. In one case the mischief was limited to the external auditory meatus, and consisted in a hæmorrhage into the lining membrane and periosteum of the lower wall. In another the meatus contained a still larger clot, and in the middle ear was a quantity of semi-solid creamy pus, which filled the chamber and had escaped into the external auditory meatus through the membrana tympani, which was softened and perforated. The ossicula were displaced with the exception of the stapes. The liquid of the internal ear was bright red in color.—*Lancet*, Nov. 19, 1881.

OPERATIVE ASSISTANCE IN INFANTILE PARALYSIS.—Some cases recently operated on by Prof. ALBERT have excited a good deal of interest. Struck by the fact that many subjects of infantile paralysis are condemned to the life-long use of more or less complicated apparatus to compensate for the loss of rigidity in the lower limbs, and that the poor cannot get such instruments, he has attempted to increase the use of the legs by operation. He excises the knee- and ankle-joints, and thus obtains bony anchylosis between the femur and tibia, and tibia, fibula, and astragalus. The rigid lower limbs in walking are swung forward by the adductor and great flexor muscles of the hip-joint, which generally retain or recover their power. This treatment has already been carried out in four cases, and a fifth is now preparing for operation.—*Lancet*, Nov. 19, 1881.

NERVE STRETCHING IN ARTIFICIAL CEREBRAL PARALYSIS AND CONTRACTURE.—At the meeting of the Société de Biologie, on November 19, M. BROWN-SEQUARD presented a monkey in whom he had four months before extirpated the motor centre of the left leg, which was followed by paralysis of the left leg, then atrophy and contracture in flexion; the limb also became 3 centimetres shorter. Twenty days before the report was made, M. Brown-Sequard stretched, with a two-pound weight, the left sciatic for five minutes; immediately afterwards the paralysis was increased, but the contracture diminished, and an hour after the experiment the limb had gained a centimetre in length, the next day one-half centimetre, and five days later both limbs were of the same length; the paralysis was also much improved after four or five days. There was then a partial return of the contracture, and the author proposed to again stretch the left sciatic, and report on the result.—*Le Progrès Médicale*, Nov. 26, 1881.

TRANSFORMATION OF ALCOHOL IN THE SYSTEM.—M. JAILLET submitted to the Société d'Émulation, the results of some recent observations on this subject. He affirms that the blood mixed with a certain quantity of alcohol in presence of oxygen, transforms alcohol into acetic ether, and that the blood globules, as has been stated by Pasteur, is a ferment cell which carries on in an alkaline solution the same process as the yeast of beer. Oxygen absorbed by the hæmoglobulin passes to the state of nascent or active oxygen, which is able to oxidise promptly and totally all the alcohol which enters the blood current. His conclusions are:

1. Alcohol ingested by the stomach is in part decomposed by the natural ferments with which it immediately comes in contact (the gastric juice, saliva, pancreatic juice, etc.), aided by the mysterious and destructive action of the liver. From this organ the alcohol passes in venous blood to the lungs, where it is widely diffused, a small quantity eliminated in the natural state, but the principal part is transformed into acetic ether. Finally the oxidation of the alcohol is accomplished in the systemic circulation where the acetates formed are totally burned.

2. When alcohol is absorbed after subcutaneous administration, the conditions are changed. The alcohol immediately enters the systemic circulation, arrives at the heart, then the lungs, and as it reaches these organs quickly and in large quantity, it is freely eliminated, as shown by MM. Perrin, Duroy, and Lallemand. Administered subcutaneously, there can be no action of the ferments of the organism; the liver does not affect its disintegration, for the alcohol has meanwhile been imbibed by all the tissues, and is diffused generally, without having been subjected to any modifying influences.

3. Alcohol is a substance which arrests respiration by preventing hæmatosis; in a word, alcohol asphyxiates without being in itself a poison. In the process of its transformation into acetic acid alcohol utilizes the oxygen being conveyed to the tissues by the blood globules, and it thus diminishes combustion in the body. This fact explains its antipyretic action. Death by alcohol is an asphyxia by carbonic acid, and we have found in animals and in man all the symptoms and the anatomical conditions of this asphyxia. It can thus be readily comprehended why alcohol, in the form of vapor, is so much more dangerous than alcoholic drinks, and produces so much more rapidly serious symptoms of poisoning.—*Journal de Thérapeutique*, Oct. 10, 1881.

PHENOMENAL TEMPERATURES.—Dr. Mahomed narrated to the Clinical Society of London (*Lancet*, November 5, 1881) the case of a hysterical female who was able to develop, or, at least, register on the thermometer, any temperature desired, 128° F. being recorded in one instance. Indeed, she appears generally to have been limited merely by the length of the scale of the thermometer, the index being usually lodged in the expansion at the top. She was only able to develop these temperatures with registering thermometers in the mouth and axilla, and then only when motion of the arms was not prevented, while surface thermometers gave a normal temperature. Dr. Mahomed remarked that it was easy to send the index of an ordinary clinical thermometer up to the top, in from ten to fifteen seconds, by rubbing it between the slightly moistened finger and thumb, exerting at the same time considerable pressure on the bulb. The same result can be obtained by enveloping the bulb of the thermometer in several folds of silk and placing it in the mouth, and then inspiring by the nose and expiring by the mouth; the result, no doubt, is produced by the evolution of the latent heat of the watery vapor of the breath as it becomes condensed upon the silk. The method used by the above case was not discovered.

In the same journal, Dr. Stephen Mackenzie reports a case of excessively high temperature in a woman who, after puzzling her physicians for some time, confessed that she produced the high temperature by poultices, hot bottles, etc.

TREATMENT OF HYDROCELE.—Dr. T. L. OGIER, of Charleston, S. C., advises the injection of about thirty drops of the undiluted compound tincture of iodine directly into the sac of the *tunica vaginalis testes*, without drawing off the effusion, in cases where a radical cure is desired, and where confinement must be avoided. He repeats the injection on alternate days, and states that in sixteen cases this treatment has been followed by the complete and permanent absorption of the fluid without any pain or inconvenience to the patients, and without confining them to the house. During the treatment, Dr. Ogier recommends the use of a suspensory bag, which is to be gradually tightened as the swelling subsides.—*Gaillard's Med. Journ.*, Sept., 1881.

PROLONGED DILATATION OF THE ŒSOPHAGUS.—Dr. M. KRISHABER gives the following conclusions in a recent paper on this subject:

1. The œsophagus will tolerate a bougie for an indefinite period. (He reports cases in which the sound was retained for 305, 46, 165, and 251 days.)

2. The sound should be introduced through one of the nostrils, and not by the mouth.

3. The permanent presence of the sound permits the dilatation of the stricture to a sufficient degree to render the introducing of gradually increasing sizes possible, exactly as is practised in cases of urethral stricture.

4. A gum œsopageal sound should be introduced in the first instance, and, after remaining in place for a few days, should be replaced by a softer and more easily tolerated rubber sound.

5. Feeding is absolutely assured by this method, and false passages, as are apt to be made in intermittent catheterization, are avoided.

6. In cases where the stricture necessitates œsophagotomy, the sound should be placed in position as soon as the incision is made, and allowed to remain, so that cicatrization will occur around it, and obliteration of the œsophagus be prevented.

7. Besides the above-mentioned uses of the sound, it may be left in position for conducting the nourishment of phthisical patients, paralytics, etc.

8. It is also of great use in operations on the face, mouth, and naso-pharynx.

9. In these latter cases, the sound should be placed in position several days before the operation, and allowed to remain until the cure is complete.—*Ann. des Maladies de l' Oreille, et du Larynx*, Nov., 1881.

THE PARTICIPATION OF THE LIVER IN THE PRODUCTION OF UREA.—In order to obtain an exact appreciation of the share attributable to the liver in the production of urea, SOLHIKOFF (*Petersburger Medical Wochenschrift*, No. 51, 1880,) conceived the idea of connecting, in large dogs, the vena porta directly with the external jugular by means of a rubber tube, an operation which, when accomplished with due precautions, is relatively well borne. When the communication is established between the venous trunks, the blood-pressure is at first depressed, but soon regains its normal height; but the urinary secretion ceases completely, and does not become re-established until urea is injected into the blood of the animal. The injections of urea cause no elevation of blood-pressure, but may sometimes even produce a depression. Previous section of the splanchnic nerves does not modify these results.

As control experiments, the author connected the crural vein with the jugular, and found that the urinary secretion was not modified. He concludes, therefore, that it is the blood coming from the liver which throws into the circulation the urea which is to be removed by the kidneys.—*Gazette Médical de Paris*, Nov. 12, 1881.

COMMUNICATION OF SYPHILIS BY SKIN-GRAFTING.—Dr. DEUBEL communicated the following case to the Société Médical des Hopitaux: A man, aged forty-nine, who had never contracted venereal disease, became, in January, 1881, the subject of gangrenous erysipelas of the thigh, which was attended with a large ulceration, having its starting point in the superficial ulceration of some hæmorrhoids, that, except at some isolated points, refused to cicatrize. On March 7, forty-five dermo-epidermic grafts, furnished by five persons, were inserted, and thirty-three of these contracted adhesions; and twenty other grafts taken from seven persons, aged from twenty to forty years, were placed on another part of the wound on the 23d, thirty of the number retaining their vitality. Grafts from the mucous membrane of the mouth of a rabbit were also employed, and on the 23d of March forty new grafts, taken from persons aged from twelve to fifty-four years, were applied. Cicatrization went on satisfactorily until April 5, when ulceration commenced in the now almost cicatrized wound where the first grafts had been planted, and soon destroyed the cicatrization. The grafts applied on the second occasion did not ulcerate, but became pale and fell off. The new ulceration had a syphilitic aspect; but the man's wife, who had nursed him, having also been seized with erysipelas which proved fatal, and a lodger suffering from lymphangitis, it was concluded that the whole had arisen from infectious causes due to the very unsanitary condition of the abode in which they all resided. The ulcerations improved on being touched with nitrate of silver, but new ones kept appearing during the next three months, and ten weeks after the first application of the grafts the skin and scalp became the seat of syphilitic eruption, and some weeks later the mucous membrane of the mouth was affected. A mercurial and iodide treatment was put into force, and eight months after the first appearance of the erysipelas the breach of surface became entirely cicatrized. It turned out that a son, who had furnished some of the grafts, was the subject of syphilis.—*Gaz. Méd. de Paris*, Nov. 5, 1881.

BELL'S INDUCTION BALANCE.—At a recent meeting of the Académie des Sciences (*L' Union Médical*, Nov. 12, 1881), M. ANTOINE BREGUET read a note from Mr. A. Graham Bell, on an apparatus which may be considered as a modification of the well-known induction balance of Hughes, and which permits of the localization—without pain to the patient, as no sounds are used—of any metallic substance in the body.

The instrument is composed essentially of a system of two flat bobbins, parallel, and so placed one above the other that the border of each lies near the axis of the other. One of these bobbins, wound with coarse wire, is the primary circuit; the other, wrapped with fine wire, is the secondary circuit. The two bobbins are together immersed in a mass of paraffine, and placed in the interior of a plate of wood furnished with a handle. A vibratory current, coming from a battery, traverses the primary circuit, while an ordinary telephone is included in the secondary circuit.

Under these conditions, no sound can be detected in the telephone; but if one brings any metallic substance whatever near the junction of the two bobbins, the silence will be broken by a sound which will depend in intensity on the nature, form, and distance of the metallic body. It may be remarked in this connection, that the most favorable shape of the projectile is that of a flat disk, parallel to the surface of the skin, and the most unfavorable is when the axis of the disk is parallel to the surface.

It is difficult, in practice, to secure the exact adjustment of the relation in position of the two bobbins: it is, therefore, convenient to introduce into the primary and secondary circuit two other bobbins, analogous to the first but much smaller, whose surface of contact can be increased or diminished by a micrometer screw, and the telephone reduced to complete silence. If it is wished to determine the depth at which the metallic body lies, its form, mode of presentation, and substance must first be known. These being known, it is only necessary to throw the bobbins sufficiently out of contact, while applied to the skin, to cause the telephone again to show silence. After that, withdrawing the apparatus, a body similar to the one explored is approached until the silence is again reproduced. The distance at which this occurs in the second instance is the measure for the distance to be determined.

Prof. Bell's note, illustrated with wood-cuts, has also appeared in English in the *American Journal of Science* for Jan., 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances for the NEWS may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,

NOS. 706 & 708 SANSOM STREET,

PHILADELPHIA, PA.

SATURDAY, JANUARY 14, 1882.

LESSONS OF THE GUITEAU TRIAL.

WITH Guiteau and his trial our readers, probably, have had something of a surfeit, but as journalists it is our duty to utilize any aspect of the case which may be of interest. The assassin is a phenomenon —an object of interest alike to the sociologist and to the psychologist. Inheriting with his French name some distinctively French characteristics, and influenced in his moral and mental development by the forces of the social life about him, his present state is a logical outcome, and he is a not inconsistent product of some elements in our American civilization. Vain, egotistical, and ignorant, he received sufficient education to give still more obliquity to his ill-balanced faculties. Bent on making a noise in the world, he tries, in turn, theology, law, politics, lecturing—anything by which he may achieve notoriety and be spoken of by the newspapers. These failing, what expedient more natural than some desperate deed, which will surely cause all eyes to turn on him. He is a type of a class becoming, unhappily, too common. A wild passion for notoriety, the outgrowth of a faulty training, half-education, and a literature composed of newspapers and dime novels, are developing a class of Guiteaus which seems likely to become too numerous in this country.

The Guiteau trial has awakened renewed interest in the question of the proper methods of utilizing expert testimony. As is usual, we have had exhibited the unseemly spectacle of experts arrayed on the two sides like so many paid advocates. The public, the lawyers, and even the wretched assassin, must be excused if they see in this only a willingness on the part of experts to give testimony on any side to which their interests may incline them. Need we be surprised that counsel take every opportunity to belittle their attainments and impugn their honesty? This state of feeling was shown in the contest between the attorneys for the prosecution and Dr. Spitzka. Because the latter is a professor in a veterinary college, he was contemptuously styled "a horse-doctor." The sympathy which the medical profession would have for Dr. Spitzka, as an expert of high attainments who had suffered most outrageous indignity from counsel whilst before the court in his proper character, is, unfortunately, destroyed by his treatment of his fellow-experts. To characterize those who differ from him as fools or knaves, is an unwarrantable abuse of his position, and an act of professional discourtesy for which he ought to be disciplined. There is much in the conduct of many of the experts to admire. Some of them came to Washington to testify their belief in the insanity of Guiteau, but on a careful study of the criminal himself, they were constrained to form a different opinion, in which all intelligent persons competent to form a judgment will probably concur. It is much to their credit that they were not afraid to change their opinions. Far different was the conduct of Dr. Spitzka. Making up his opinion in advance from insufficient data, he adhered to it with unreasoning obstinacy, and illustrated the nature of his mental processes by assuming his own infallibility, and condemning those as fools who ventured to express opposite opinions.

CRANIOLOGICAL CHARACTERISTICS OF ASSASSINS.

AN expert for the defence in the Guiteau trial has enlarged on the importance of certain craniological peculiarities of the assassin's head. The technical terms in which Dr. Spitzka defined and classified the malformation astonished the reporters. Our lay contemporaries, on a sudden, have taken to the discussion of cranial topography, but the most important contributions are made by the hatters, who, producing their charts, have disclosed to us how many of our reputable citizens should, if their cranial conformation is to decide, be assigned to the gallows or to a mad-house. The hatters say that symmetry of the head is rather exceptional and abnormal, and that even considerable deformity is not incompatible with the possession of superior powers of mind.

It is very satisfactory, at this juncture, to be able to call in for examination some independent and unbiassed testimony. Whilst discussion is going on over the head of the wretch Guiteau, a valuable contribution to the cranial characteristics of assassins has appeared in the *Revue Internationale des Sciences Biologiques*, No. 11, by MM. Heger and Dallemagne. Their study is based on a series of assassins executed in Belgium, who do not constitute a species

apart from the type to which they belong, say these authors. The lack of resemblance in the crania of the different series of assassins conducts them to the conclusion that it is impossible to formulate a theory of the craniological characteristics which will include them. On the other hand, the study of these characteristics has demonstrated that amongst assassins there are many whose cranial conformation reveals mental inferiority.

Thus it appears that, in the present state of knowledge of the subject, it is hazardous to draw conclusions from the cranial conformation. Although general conclusions may be drawn from the shape of the head in regard to the mental power of individuals, the facts do not warrant the attempt to define the characteristics belonging to assassins. The subject of cerebral localization is not in a sufficiently advanced state to permit even an approximative representation of the parts of the brain purely intellectual in function, and of those devoted to the moral or affective faculties. How much more obscure the subject, when the surface topography of the cranium enters into consideration! It is, of course, perfectly well known that the protuberances and depressions of the exterior are imperfectly, or not at all, represented within—a fact which constitutes an insuperable objection to the doctrines and the localizations of function put forth by the phrenologists.

ARE THERE STRICTURES OF LARGE CALIBRE?

A RECENT writer, entitled to speak with authority, asserts that gonorrhœa, by reason of its great prevalence and of its remote effects, is the most prejudicial to the public health of all the venereal diseases, not excluding syphilis. This is contrary to the commonly received view, and may be rather too broad a statement; but, unquestionably, of late years the disease has assumed an increasing importance, as the constant pathological results of continued irritation of mucous passages, the reflex symptoms and ailments produced by interference with the genito-urinary tract, and the changes undergone by the bladder when its long accustomed work is notably increased, have been more fully and thoroughly recognized.

Accurate statistics on such subjects are necessarily unobtainable, but the course of reasoning which results in the conclusion above stated may be outlined as follows:

A very large percentage of adult males have been at some time the subjects of acute urethritis; in two-thirds of these the disease has been several times contracted, or has on at least one occasion run a protracted course; persistent irritation at any given point in the body results in an increase of the fibrous tissue in that region, associated with a deposit or development of new tissue of a similar character; this is especially true of mucous and submucous surfaces. Such a deposit occurring beneath the mucous membrane lining the urethra, interferes to a greater or less extent with the lumen of the canal, and thereby constitutes a stricture.

If a current of liquid be passed along a tube, a certain degree of friction proportionate to the amount and velocity of the current and the size of the tube takes place between the walls of the latter and the liquid; if the tube be narrowed at any one place, the friction is increased at that point, and, to avoid a notable diminution in velocity, the propulsive force behind the liquid must also be correspondingly increased.

Habit is a powerful agent in facilitating and governing the functions of animal life; in the case of a young adult, the bladder has, during twenty-one years, gradually accommodated its efforts and its powers to overcome a certain average amount of resistance. This equilibrium or balance between its expulsive force and its work, the result of thirty thousand distinct acts of micturition, taking an average of four daily, cannot with impunity be disturbed. The very moderate amount of prostatic enlargement which often suffices to bring on vesical troubles is an illustration of this fact.

The increased friction and resistance resulting from even a slight fibrous peri-urethral deposit disturb the normal relations of the bladder, and, by rendering it irritable, bring on one of the common symptoms of stricture—frequent micturition. The imperfect closure of the tube, the muscular action of which, at the point of deposit, is materially interfered with, causes the equally imperfect expulsion of the last drops of urine, and produces another characteristic symptom—dribbling at the end of micturition. The retention and decomposition of these last drops, together with the abnormal friction between the stream of urine and the urethral walls, give rise to a sub-acute inflammation of the mucous membrane, accompanied with a catarrhal or muco-purulent discharge, constituting the well-known condition of gleet; by reflex irritation transmitted from the area of inflammation, pains are developed in remote situations, notably in the lumbar and hypogastric regions.

We have, then, a group of symptoms apparently resulting from a sub-mucous urethral deposit and sufficiently characteristic, to wit: frequent urination, dribbling at the end of the act, gleety discharge, and certain aches or dull pains in the small of the back or over the pubes.

The relation between these symptoms and the general physical and physiological laws which have been alluded to, however crude it may appear as here briefly sketched, has been in the main accepted

as correct by the profession for many years. Probably no one would deny that in certain strictures in which the urethral calibre is markedly diminished the connection between the pathological changes and the observed indications is about as has been stated. The differences of opinion which now exist are chiefly as to the *amount* of urethral contraction which is sufficient to produce noticeable results, and here the argument must rest upon clinical observation supported by the results of autopsies. That every urethral coarctation must at some time have been a "stricture of large calibre," is a self-evident fact; and that the tendency of all such strictures is to gradually diminish the size of the urethra, and to interfere with its dilatability, is equally clear from the well-known proclivity of cicatricial tissue, wherever found, continuously and steadily to contract. This is no more and no less noticeable when that tissue is situated around the urethra than when it occupies the intertubular spaces in interstitial nephritis, strangulates and destroys the parenchyma of the liver in cirrhosis, produces induration and bronchiectasis in chronic pneumonia, or in any of the many possible directions exerts its power in the production of disease. Although, as has been said, the exact degree of contraction which renders it an active pathological factor in urethral cases is undetermined, it may yet be safely asserted that there are few surgeons at the present day who would agree with Sir Henry Thompson in the belief that the easy introduction into the bladder of a sound eighteen or nineteen millimetres in circumference is sufficient to demonstrate the non-existence of organic stricture. Indeed, the observed variations of the normal urethra are such that no special dimensions can be assigned to it as representing the precise dividing line between health and disease; the old method of regarding the size of the meatus as an indication of the normal calibre of the canal behind it being unquestionably fallacious, it having been conclusively shown that no definite relation exists between them. On the other hand, it has also been shown that there are usually certain normal variations in the calibre of the urethra, even in the spongy portion, which is now claimed with much show of truth as the most frequent seat of pathological contractions, and that it is impossible, with any of the means at our command, to distinguish between these natural irregularities and coarctations of equal calibre due to incipient strictures. The great importance of bulbous bougies in detecting, measuring, and locating stricture has, however, been more fully recognized than ever before, and coincidently the unfitness of the ordinary steel sounds for the same purpose, by reason of their weight and their conical shape.

In conclusion, it may be said that, although our knowledge is insufficient to determine in every case the exact nature or pathogenetic value of any given slight diminution in urethral calibre unattended with symptoms, we have yet abundant evidence, clinical and post-mortem, to enable us to advance, with little risk of contradiction, the following propositions, applicable to the vast majority of cases:

A patient who, after an attack of gonorrhœa, develops any or all of the above-mentioned symptoms, has in all probability a commencing stricture.

If a careful examination with a bulbous bougie reveal any constriction other than the one at the triangular ligament, which is known to be normal, it may with confidence be considered as due to a fibrous deposit in the sub-mucous tissue, and the symptoms may be referred to it.

This condition, though yielding readily to proper treatment, is, if neglected, productive of serious consequences, which, in exceptional instances, may even imperil life, through continuous irritation of that portion of the genito-urinary tract posterior to the contraction.

Such sequelæ are to be expected in a large proportion of cases of long-continued or oft-repeated gonorrhœa, are possibly even numerous enough to justify the assertion quoted at the head of this article, and, at any rate, in view of their extreme frequency, demand the thoughtful consideration of the profession.

COMPULSORY VACCINATION.

THE very general prevalence of small-pox throughout the country is naturally directing attention to the means of its prevention. No one at the present day can plead ignorance of the protective power of vaccination when properly performed; and it is therefore surprising that, in the very face of danger, the proportion of the inhabitants of every community who have not availed themselves of this proved means of safety remains a very considerable one. How to secure universal vaccination, or, in other words, how to prevent the repeated incursions of epidemic small-pox, is a problem which at this time deserves most serious consideration. Its solution would seem to lie in a successful effort to make vaccination compulsory either by fine or by imposing disabilities for its non-performance. This latter plan has already been adopted to a considerable extent, but its availability must necessarily be limited; and it would therefore appear that nothing short of direct compulsion by law will secure the desired result. Compulsory vaccination has never been adopted in this country to any great extent, but there can be no valid reason why the American people should hesitate to sanction a measure which, if wisely enacted, would redound to the benefit of the whole country. The idea of its conflicting with

the right of unmolested enjoyment of personal liberty, is pure sentimentalism. The liberty to spread disease by neglecting or refusing to observe the means of prevention known to be safe and efficient, and which is within the reach of every one, is a liberty which should be abridged by the enforcement of wise laws.

Already there can be discerned, in recent legislation on the subject of vaccination, the evidences of a better appreciation of the importance of this question. The National Board of Health have adopted the following rules, in conformity with the provisions of the act of June 2, 1879, to prevent the introduction of contagious and infectious diseases into the United States from foreign countries, and from one State to another, which rules were approved by the President, November 11, 1881, and are now in operation, to wit:

1. That all persons coming from or through any foreign port or place in which small-pox exists, who, after the 14th day of November, 1881, shall arrive at any port of entry within the United States, shall be subjected to examination as regards their protection from that disease by the proper health authorities of the State within which such port lies, or in case such authorities shall fail or refuse to enforce this rule, then by some officer or other proper person, to be designated by the President of the United States.

2. That in case any person so arriving shall refuse to submit to such examination, or upon undergoing the same shall be found not sufficiently protected from small-pox, such person, and in case he or she be not *sui juris*, then also the person having him or her under charge, shall be detained in quarantine until he or she shall have been properly vaccinated, or shall have passed the period of incubation from date of last exposure.

Still more recently, the City Councils of Richmond, Va., have passed an ordinance requiring the immediate vaccination of all residents who have not been vaccinated within the past twelve months, "except in such cases as any regularly licensed physician shall declare it to be injurious or unnecessary." Its violation is made punishable by fine. The ordinance is not so complete as it might be, and bears evidence of hasty preparation, but the effect of its passage cannot be otherwise than beneficial. If a like energetic and radical crusade against small-pox were undertaken throughout the country, this disease would soon cease to commit the ravages which are now, unfortunately, of very common occurrence.

THE PROSECUTION OF DR. FERRIER BY THE ANTI-VIVISECTION SOCIETY.

THE Secretary of the Antivivisection Society in England, Miss Frances Power Cobbe, has been very active in denouncing the vivisectionists since the failure to convict Dr. Ferrier. She is not sparing in her abuse of the medical profession, also. As is not unusual, the zeal of these pretended humanitarians quite outruns their discretion. Dr. Ferrier was dragged before the police court for a violation of the vivisection act, as will be seen in our London news, when the supposed offence was committed by Dr. Yeo, who had a license in proper form. The expense and trouble suffered by Dr. Ferrier on account of the misdirected zeal of the Society, for which they offered no excuse or apology, has had the effect of increasing the dissatisfaction felt in the operations of the vivisection act. In an interesting letter to the New York *Tribune* from its London correspondent, we find a calm and judicial statement of the vivisection question, and an account of the injury done to scientific work—at least on the physiological side—which has been for the most part suspended. The correspondent shows that the abusive communications printed by Miss Cobbe, and the bad effect of the vivisection law in stopping original researches in England, are stirring up an opposition to this intemperate law, which will probably result in its modification. It is a hopeful indication when such an intelligent and appreciative discussion of the subject appears in a daily paper from its London correspondent.

THE VIVISECTION LAW AND THE CHINESE OPIUM TRAFFIC.

IT is not possible to reconcile the humanitarian sentiment of the English which has suppressed vivisection as a means of scientific research and that aggressive self-interest which has forced the opium traffic on China. The members of Parliament who enact laws against experimentation on animals for a scientific purpose, will shoot pigeons in hundreds on a wager, and pursue birds and beasts to death for mere sport. They, further, protect animals for their own sports by stringent game laws, and force opium on the poor Chinese to keep up the revenues of India. In the issue of the *Medical Times and Gazette* for December 10, 1881, we find an article on the opium traffic, in which a defence of the British policy is implied in the arguments for the use of this drug.

It appears there are 2,000,000 of Chinese who expend a daily average of 5*d.* to 11*d.* (10 to 22 cents) per person for smoking opium. The annual expenditure of China for opium is £25,000,000 (nearly $125,000,000), one-half of which is obtained from India. The traffic is justified on the following grounds (having been forced on China by the bayonet):

"Opium has a dietetic as well as a medicinal value. It is customary for the reformers of society, with reference to this drug and alcohol, to bracket them together in one sweeping condemnation; but,

while the latter is simply a temporary stimulant, for which there are substitutes equally powerful, though not so pleasant to swallow, the former tranquillizes, arrests waste of tissue—being in this respect to the poor Chinamen what tea is to the same class in the United Kingdom—and in time of famine takes the place even of food; to say nothing of its incommutable value as a medicine. Its reception into the heart of society is too universal and deep for Acts of Parliament or imperial decrees to be efficacious in preventing its consumption." And yet we are told in another part of the same article, "it seems at first sight somewhat remarkable that, because two-thirds of one per cent. of the 300,000,000 of the people of China choose to consume opium—some only of these to an immoderate extent—the well-wishers of the country should so earnestly desire to do away with the consumption of the drug altogether."

FIRE-ESCAPES FOR HOSPITALS.

THE recent fire in a Philadelphia mill, which caused so fearful a loss of life, from want of any fire-escapes, should call the attention of all our hospital authorities to the need for fire-escapes. If they be necessary in mills, hotels, and other buildings in which the active and the well are employed, the need is far more pressing for numerous escapes in buildings in which many if not most of the inmates are to a certain extent disabled. The absolutely helpless could scarcely escape even with assistance, but we should beware of penning up patients who are not bed-ridden, without sufficient means of escape, in third and fourth stories, all ready for a horrible holocaust. We are glad that in Philadelphia the Mayor and the City Councils are moving in the matter, and we trust that our hospitals, not only here but everywhere, will act cordially, quickly, and efficiently.

If our City Fire Departments had suitable mattresses to carry quickly to fires, or stout sheets, as it seems were used in Vienna in the fire at the Ring Theatre, either of which would break the fall for those who must jump, they would often have a valuable means of saving life.

SIR JAMES PAGET, BART.

SIR JAMES PAGET'S many friends and admirers on this side of the Atlantic, will learn with regret that at the end of November he was confined to his bed by an attack of pneumonia, similar to other seizures previously experienced by him since he suffered from blood-poisoning. We are happy to be able to state that at the latest accounts he was decidedly better and had gone to the south of France to recuperate his health.

REVIEWS.

MR. SPENCER WELLS'S NOTEBOOK FOR CASES OF OVARIAN AND OTHER ABDOMINAL TUMORS. *Sixth Edition.* London: J. & A. Churchhill, 1881.

To surgeons who practice ovariotomy and abdominal surgery Mr. Wells's notebook is of great service. He who follows it cannot avoid making, what is absolutely essential in cases of abdominal growths, a careful examination, and careful examinations lead to correct diagnoses. The plan of the notebook is such as will obtain, under proper headings, a complete history of each case, with record of diagnosis, prognosis, treatment, medical or surgical, and results of treatment.

One or two points, in the examination of the pelvis, are worthy of special note. First, that in cases of probable pregnancy the sound should not be used to ascertain the length of the uterine cavity, and, second, examination of the uterus by the rectum affords much more information than is commonly supposed. This method of examination should always be employed in conjunction with those which it may be deemed safe to make.

In this edition, the sixth, the author adds a note as to the antiseptic precautions he has employed in his later operations. In January, 1878, he began to employ the complete antiseptic system, and from that date to the issue of the edition, April, 1881, he performed 137 operations, with 13 deaths—a mortality of 9.4 per cent. He states, as his belief, that "this diminishing death-rate is mainly due to the additional antiseptic precautions." This conclusion will be accepted, it is believed without question, by surgeons in this country who have performed ovariotomy under the old and new methods.

ANTISEPTIC SURGERY. By Dr. JUST LUCAS-CHAMPIONNIÈRE. Translated from the second edition by FREDERIC HENRY GERRISH, M.D. 4to, pp. 239. Portland: Loring, Short & Harman, 1881.

The student who desires to learn the antiseptic theory, the preparation and application of the Listerian dressings, and the adaptation of the system to all sorts of operations and all regions of the body, will find in this book a satisfactory guide as far as the subject can be treated in so brief a space. That the author has the courage of his antiseptic convictions, is proved by the fact that, even in obstetric patients upon whom he has operated, he allows his class of students to make daily vaginal examinations, and his internes to dissect and make post-mortems *ad libitum*, provided they use antiseptic precautions. In spite of this, too, his mortality has been very low. As a commentary, not very flattering to the administration of French hospitals, on page 175 (the appropriate "running title" of which is "a plea for cleanliness") he states that "in Paris all the habits of the students are in need of reform. I do not blame them; it is physically impossible for them to be surgically neat in the hospital. . . . At present not only is nobody compelled to wash his hands, but it is almost impossible to do it in a hospital, so poor are the facilities."

Dr. Gerrish has translated the book admirably; in fact, it can scarcely be discovered that the book is a translation. But we are disposed to take exception to the use of so rare a word as "germ-bearing *epithem*" for "application" or "dressing," and still more to the imported phrase, especially affected by many of our German scholars, "to *make* an operation." Dr. Gerrish even goes farther, and speaks of "making sutures."

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 5, 1882.

FORDYCE BARKER, M.D., PRESIDENT, IN THE CHAIR.

The annual election resulted as follows: For Vice-President, H. T. Hanks, M.D.; for Trustee, C. Fayette Taylor, M.D.; for Member of Committee on Admissions, J. E. Janvrin, M.D.; for Member of Committee on Ethics, Chas. A. Leale, M.D.; for Member of Committee on Education, F. A. Burrall, M.D.; for Member of Committee on Library, J. C. Peters, M.D.; for Delegates to Medical Society State of New York, Drs. A. M. Jacobus, L. Elsberg, C. C. Lee, Everett Herrick, F. A. Birdsall.

The scientific paper of the evening was by SAMUEL SEXTON, M.D., and was entitled:

The Treatment of Diseases of the Middle Ear and Contiguous Parts by Milder Measures than those Commonly in Vogue.—The author avoided such details as were only of interest to otologists. The causes of suppurative diseases of the ear were arranged under three heads: first, nervous sympathy, as from dental or uterine irritation; second, extension of catarrhal inflammation from the naso-pharynx through the Eustachian tube to the ear; and third, mechanical or direct influences, as the entrance of water in bathing and the use of the nasal douche. More than one of these causes might be active at the same time. His experience had been, that among adults the graver cases occurred more frequently in males. Of such cases one-half were consecutive to acute attacks. Among children, it was his impression that the graver cases occurred more frequently in females. Many cases of acute aural catarrh ran a mild course. The secretions of the middle ear were slight in quantity, and could escape through the Eustachian tube, or where this was not possible an outlet was afforded by the rupturing of the drum-head, which healed up very rapidly under favorable circumstances. If such simple cases, however, were treated by violent measures, such as leeching, blistering, and untimely incision of any of the tissues about the ear, or by vigorous inflations of the tympanum, they might take on a severe form of inflammation, and adjacent structures might then rapidly become involved. He would not dogmatically assert that all cases thus treated would take such a course, but he was fully convinced that in a large number of instances the cases would do better without them, and many times they did much harm. In a certain number of cases, an untoward course might be expected from the beginning of the attack.

The extension of this affection to contiguous parts, was divided for convenience of description, as follows: 1. Catarrhal inflammation of the air-cells of the mastoid; 2. Periostitis of the external auditory canal; 3, Periostitis externa. An extended account of the etiology, symptoms, and pathology of inflammatory conditions extending to parts contiguous to the middle ear, was given. It was thought that a differential diagnosis of the invasions of these conditions, and a knowledge of the diagnostic value of pain as a symptom, would do much towards a more rational treatment of aural diseases. The diagnosis of simple hyperæmia of the mucous lining of the mastoid air-cells was difficult, as the symptoms were not always different from those of middle-ear catarrh, but when the mucous periosteal lining was attacked there would be an increase of pain. The attack might be ushered in by chills, and the temperature and pulse, in severe cases, would be characteristic of acute inflammation, and the pains would be non-paroxysmal. The degree of pain was not always indicative of the gravity of the disease. Inasmuch as acute middle-ear inflammation was liable to take on a severe form, it was desirable to prevent this by treatment, and it was thought this could be done by milder measures than those commonly in vogue. It was commonly believed that syringing and poulticing were harmless. Both were liable to a great deal of harm, and the relief afforded by leeches might be more than compensated for by the irritation caused by their sharp bites, and the bungling efforts made in stopping bleeding after they dropped off. The large coagula entangled in pellets of cotton-wool used to arrest hæmorrhage, were also liable to irritate the parts, especially in children. Blisters and the tincture of iodine applied over the mastoid, or in front of the ear, were not without their evil effects, and instillations of astringent injections were often very injurious. Inflations of the tympanum were sometimes both painful and harmful. The propriety of attempting to increase the acuteness of hearing in any acute case, was questioned. These procedures might transform a simple acute, purulent inflammation of the middle ear into one of more or less severity, or, at least, protract the disease very much.

Some years ago certain neglects on the part of patients, and certain accidents led Dr. Sexton to make observations in regard to the efficacy of milder measures in the treatment of these cases than those commonly used. Pursuing this line of study some general or constitutional remedies were brought to his notice, the use of which had been very satisfactory. Rest was important; that is, the inflamed organ should be but little disturbed by local applications at first. If the patient was seen before the ear discharged, and the drum-head was found inflamed, but not greatly bulged out by pressure of secretions, it should not be subjected to any treatment whatever. If thickened and more resisting and violently distended, the question of paracentesis presented itself. Under these circumstances he had been accustomed to give the patient the benefit of the doubt, when any existed, and upon the whole, he had not regretted the postponement of the operation. It was well known that the drum-head gave way, when not thickened, without any one being conscious of the fact, before a serous discharge appeared. Even in adults the operation was not always easy to perform, and in weak and debilitated persons, and especially in children, an anæsthetic was usually required. He was not in the habit of performing the operation without getting a good view of the drum, for when there was swelling of the inner extremity of the external auditory canal to such an extent as to prevent inspection, we were warranted in concluding that the pain depended upon other causes than distention of the membrane, namely, an inflammation of the periosteal coat of the canal. When the ear began to discharge, gentle wiping with absorbent cotton-wool was preferable to syringing. Later, when the secretion became more viscid, syringing was sometimes advisable in order to cleanse the canal. In the meantime attention to remote influences was demanded, otherwise the local treatment would be ineffectual. In the beginning, when the discharge was slight, boracic acid with calendula, was sometimes most efficacious. It was applied in the dry state, a small quantity being introduced and allowed to come in contact with the drum-head, and there remain until carried away by the discharge, when it should be re-applied. When the discharge was excessive this was still beneficial but not so satisfactory. In the author's experience the healing effect of this preparation had been very well shown. By such measures patients would sometimes get well in a week, or less time. In the greater number of cases recovery did not take

place so rapidly, and constitutional treatment would be required.

There were some remedies which had not been generally adopted in the treatment of aural inflammation that had, in his hands, proved to be of great value. One of the most important of these was *calx sulphurata*, or sulphurated lime. Dr. Sexton first used this some six years ago in furuncular disease, and the results were so gratifying that he published them in the *American Journal of Otology* for January, 1879. Experience had confirmed the statements then made. He had found it to exert a more favorable influence over acute aural inflammations than hitherto obtained by any other treatment. After explaining the action of the remedy, he stated that he gave it in doses of one-half grain, repeated every three or four hours, and seldom found it necessary to increase the dose. A smaller dose was sometimes preferable, especially in children. He preferred to use it in the form of gelatin-coated pills, unless it was desirable not to administer a pill, or when a smaller dose was indicated. For this purpose the triturations of "*hepar sulphur*" of the homœopathists were satisfactory. So gratifying had been his results in the use of this drug, that he had not felt called upon to leech patients for years, however severe the inflammation. He was rarely obliged to use the knife for the relief of inflamed tissues anywhere about the ear, unless for the evacuation of large collections of pus already formed.

In periostitis externa, where pus threatened to form, he regarded the usual operation of cutting down to the bone, for the relief of this condition, as not only unnecessary for the cure, but also a cruel infliction on the patient, and likely, in many instances, to aggravate existing conditions. The early use of calcium sulphide usually relieved all symptoms very promptly. Sometimes, though the inflammation yielded, the pains continued. They were not constant, were worse at night, and seemed best borne when the patient was sitting up or walking about. For the relief of these pains there were several remedies which should be tried before resorting to the use of powerful anodynes, such as morphia. The latter, when employed excessively, interfered with nutrition. The remedies alluded to were aconite, gelsemium, and pulsatilla. These might be employed in varying quantities from a drop to a minute portion of that dose, given every few minutes, or every few hours, according to the age of the patient and the urgency of the symptoms. Pulsatilla seemed to act best in acute aural disease of children. The effects of the other two drugs seemed to be about the same, though it would sometimes be found advantageous to give one first and afterwards the other. When the inflammation extended to the cells of the mastoid, the effect of sulphide of calcium was most beneficial. When used early, the more serious consequences of inflammation were not often observed. He had never been obliged to employ the trephine, nor had he ever seen any results that caused him to regret that this radical procedure had not been adopted. He thought, when periostitis externa was attended with much pain, that patients were sometimes subjected to unnecessarily severe treatment—to operations which neither always relieved the pains, nor prevented brain trouble. The existence of pain was not always sufficient to indicate the necessity of trephining, for it was not always pathognomonic of extension to the brain. The results of this operation were by no means as harmless as one might be led to think from its simplicity. Dr. Sexton thought the operation had been needlessly performed in many instances. It was difficult to understand how pain could always be relieved by it, especially when cerebral disease arose from direct transmission from the middle ear, or from previous absorption from mastoid disease; and when neuralgic pains had their origin in other parts, relief was always improbable. No necessity for considering the advantages of the operation had arisen in his own practice. In caries of the mastoid cells, it was important to maintain a free opening, and to remove loose sequestra.

Dr. C. H. BURNETT, of Philadelphia, being introduced by the President, and requested to open the discussion, remarked that he could endorse all the author of the paper had said, in so far as his experience went. There were some points mentioned, however, in which he had no experience. Many times neuralgic conditions might be mistaken for inflammatory conditions. He had seen some cases in which, when the surgeon came to operate, there was added to the original complaint, an artificial disease, if he might so speak, as a consequence of the operation. These were probably among the most important cases of aural disease with which we meet. Dr. Burnett had had an opportunity of studying the natural history of mastoid disease, both when it was allowed to run its natural course, and when it arose from traumatic influences. As an example of the first class of cases, he would cite one which came under his observation several years ago. He was asked to see a physician, having what he thought to be middle-ear disease. None of the five physicians present were willing to operate. The patient was recovering from pneumonia, and complained of pain and deafness in one ear. Upon inspection, the drum-head was found to be bulging, and he thought required incision. The patient begged off for a day, and on the next morning it was found that perforation had taken place, which resulted in an amelioration of these symptoms for a time; but afterwards, the more severe symptoms of mastoid disease developed. The speaker was absent from the city several days, but from the attending physician, and from carefully-kept notes by the patient's wife, he learned that the case had passed through the regular course of mastoid disease. No operation was done further than keeping the membrana tympani open by frequent punctures, as requested by the patient. Finally there was a discharge of purulent matter, such as is frequently found coming from the cortical cells through the mastoid portion. The probe revealed an entrance into the cavity an inch and a half from the point of its insertion; it passed through bone. This was a case which was not operated upon, though it perhaps should have been. Dr. Burnett thought the patient recovered by a process of natural relief. He was now perfectly well, and had no trouble in his ear. Another case, not so severe, was detailed. A gentleman, after bathing, gave evidence of inflammation in the tympanic cavity, and of mastoid disease. The drum-head was opened, and a little mucus came out, but there was no relief of pain. Wildes's operation was suggested, but owing to the miscarrying of messages, the case was not seen for several days, and the patient recovered without operation.

As an example of cases arising traumatically, he would cite the history of a young man in the Presbyterian Hospital in Philadelphia. The patient was twenty-four years of age, and was a brakesman. He was found in the car in an insensible condition, with an extensive injury of the left ear. There was an immense wound, extending through the auricle and mastoid canal, and there was facial paralysis. At the end of two weeks he suddenly recovered consciousness, but the paralysis remained the same. He complained of intense headache upon the left side, which was the injured side. The wound was an inch and a half deep as viewed from the auricle, and one could look through the large opening into the mastoid cavity. A piece of bone, evidently a mastoid sequestrum, was taken out. The wound healed rapidly, and the hearing became

very good, though not quite normal; but the facial paralysis remained unaltered. The piece of bone was taken out behind the auricle, and was evidently a piece of the posterior wall of the auditory canal. Running through it was a canal, evidently a portion of the facial canal somewhere above the mastoid foramen.

The speaker had never used sulphide of calcium except in one case of furuncular disease of the ear, occurring in a strong, robust man of thirty years of age. In this case entire cessation of local treatment was recommended. The patient recovered, and had no further recurrence of furuncles. He believed, however, as stated by the essayist, that in this substance we had a valuable remedy as a resolvent. He wished to inquire whether the administration of this drug should be confined to those patients who were of full habit, or whether it was to be given as well to cachectic and debilitated subjects.

Dr. ROOSA remarked, that he found nothing to criticise in that portion of the paper which treated of the etiology of aural diseases, except, perhaps, that the author laid more stress upon reflex influences than most aurists did or had done. He considered the recommendations in regard to the treatment of necrosis and removal of granulations to be sound surgical practice; but with regard to all the rest of the paper—with regard to the administration of the sulphide of calcium, pulsatilla, and abstinence from surgical interference—he was so impressed with the unsoundness of the essayist's doctrines, that he felt some embarrassment in speaking. He had been taught that free vent should be given to pus, that swollen and inflamed periosteal tissue should be incised, and he had found in his practice that this teaching was correct. As regards the action of sulphide of calcium, he had tried it in circumscribed inflammation of the external auditory canal, and in diffuse inflammation, but he had never known it to influence the progress of the disease. He had never dared to try it in acute tympanic inflammation. He would endeavor to formulate the principles of practice to which he still adhered, and which he had already expressed in a public way, and which he did not believe had been overturned. Given a red membrana tympani, a *serious* pain referred to the ear, he believed that unless speedy relief was afforded by the warm douche, there was no remedy to be compared, as yet, to leeches. He believed if the drum-head be bulging, it was much safer and quicker, although many patients got well without it, to incise it with a needle. He admitted that there were mastoid inflammations that needed no incision. He remembered an instance of this, where he was somewhat reluctantly persuaded to defer operating for a short time, and the patient recovered in a few days, but this class of cases was very limited. He was very far from thinking that every case of aural disease was to be attacked with leeches and the knife, but he did believe there were many cases in which local antiphlogistic measures, and the use of the knife were required. He found a marked resemblance between the recommendations contained in the paper and the teachings of homœopathists; they might be correct and they might be wrong. As yet, he could not believe that the principles of surgery had been turned upside down, as it seemed the essayist thought, inasmuch as he did not now see cases which required the use of leeches and the knife. He would state further, that he knew of many instances of patients having been treated with the sulphide of calcium, and who had finally been obliged to resort for relief to leeches and the knife.

Dr. O. D. POMEROY thought almost as Dr. Roosa thought, and differed almost totally from the author of the paper. He could hardly speak without heat, in attempting to combat propositions which seemed so extraordinary and monstrous, to wit, the non-opening of abscesses, the non-use of morphia to relieve pain, and the non-use of measures for the unloading of engorged blood-vessels. These well-established surgical principles seemed, according to the author of the paper, to have become of very little, if any use. The doctor had spoken of leeching as a violent measure, and likely to do harm. Leeching need not be a violent measure, and American otologists did not put six or eight leeches upon the ear. They had found one or two to be sufficient, so that the plea of depletion from their use would not do. In regard to the leech-bite, he would say that he thought it was clean cut, harmless, and almost painless. He thought the essayist was right in saying that harm might be done by bungling efforts in arresting hæmorrhage after leeching. He had observed this in several cases, and even applied leeches himself to avoid it. If there was decided acute hyperæmia of the tympanic cavity without any relaxation of tissue, the leeching could not possibly do harm. When hyperæmia of the tympanum was associated with passive congestion, he had known a dragging pain to follow leeching. This, he thought, was due to drawing blood from neighboring parts, but this was only a theory. Such pain, however, could at once be relieved by opium. He had himself had otitis too many times not to be conscious of the complete, speedy, and welcome relief afforded by leeching and opium. He wanted to say something about syringing. He admitted, if plain water (unsalted) was thrown into the tympanic cavity, it might do harm, but when the ear was properly syringed it could do no harm. The mildest application of cotton to the ear might produce worse results than proper syringing. In acute inflammation of the tympanum, when there was an excess of pressure and soreness, inflation caused pain and aggravated the case, and ought not to be done. But in acute inflammation, the drum might be quite sunken, and would require inflation. In chronic conditions, inflation was practised as a matter of course. Some years ago he published a paper bearing upon the question, as to whether redness of the drum membrane was evidence of inflation. He found, after many experiments, that in some cases there was redness of the drum membrane produced, and in others not. Hence, as there was a certain degree of violence in inflation, it should only be used to the extent necessary to keep the hearing up to the highest pitch. He believed he had not done Wildes's operation in over a year, and thought it rather unnecessary and cruel. Many times when the mastoid was red and swollen, and pitted on pressure, he relieved this condition by leeching. The essayist had found it advisable, in most cases, to postpone paracentesis, and when performed in nervous patients, or children, that an anæsthetic was necessary. Dr. Pomeroy thought that the point raised by Dr. Roosa in regard to this matter, was absolutely impregnable. He considered the operation simple. It might be done every day or two, if necessary, as Dr. Burnett has suggested. Except in the children, he thought an anæsthetic unnecessary. He was astonished almost beyond limit, by the author's statement that he had not resorted to the use of leeches in acute inflammation, for two years. He knew that much might be accomplished by other means, but it seemed impossible for him to handle certain cases without them. The essayist had spoken of frequent relapses. The speaker was in the habit, under such circumstances, of leeching his patients repeatedly. He remembered a case of catarrh of the Eustachian tube. The patient had a heavy, dull pain. He was leeched once in three or four days, and every time the hearing came up almost to the normal point. He had never used the sulphide of calcium. His assistant, however, had repeatedly employed it, and had found it to be of no avail whatever.

Dr. DAVID WEBSTER thought his own experience, for the most part, coincided with that of others, as recorded in books, namely, that these cases of chronic suppuration of the middle ear, which were so difficult to deal with, and which we did not always succeed in curing, even after the most protracted and diligent course of treatment, all originated in acute inflammation; and in a vast majority of instances, the acute trouble had had no treatment. Owing to the greater prudence on the part of patients, many more of these cases now came under treatment in the acute stage than formerly, and he failed to remember a single instance where an acute inflammation of the middle ear had been treated, from the first, according to scientific methods, as laid down in the books, that had resulted in chronic inflammation of the middle ear. He thought the general experience of aural surgeons would bear him out in this statement. There was no disease more amenable to proper treatment than acute middle-ear inflammation. He had had no personal experience in the treatment of these cases with pulsatilla, or sulphide of calcium. He wished to say, however, that he knew patients recovered with a useful organ under the old method of treatment, and that, in many cases, without treatment, the acute inflammation was followed by chronic inflammation.

Dr. SEXTON, in closing the discussion, replied first to the inquiry of Dr. Burnett, respecting the use of sulphide of calcium. Of course, age and habit did make a difference, but he had seen no case in which he had not felt justified in giving it. He thought, that since otologists had taught that the drum membrane must be punctured, and the mastoid perforated, practitioners had got into the habit of operating too often. He did not say he would never use these measures, but he did say that he had not found occasion to do so; and he did not believe that he would permit patients to suffer unnecessary pain. He was surprised at his colleague's statement, that the remedies recommended were homœopathic. Certainly all these remedies were used by other members of our profession, and in varying doses. As regards patients who had been treated with sulphide of calcium going to other practitioners for relief, he did not think that was a proper subject for discussion.

CORRESPONDENCE.

LOSS OF HEARING DUE TO PURPURIC EXTRAVASATION.

To the Editor of the Medical News:

SIR: Will you kindly give me space to report in brief a case of some interest and extreme rarity? I was consulted on October 21, by Mr. T. M. C., of Laurenceberg, Ky., who reported that on the morning of the 14th he awoke and found that he could not hear any sound on the right side. The condition was accompanied by no dizziness, or pain, or other symptom. The tuning-fork being placed on the head or on the teeth, the sound was not conveyed to the affected ear, as is the case in conditions in which there is trouble of the sound-conducting apparatus, and to an ocular inspection there appeared to be no deviation from the condition of health. By the aid of these facts we were enabled, whatever be its nature, to locate the disease in the course of the auditory nerve, either before or after its entrance in the cochela. In our attempts to discover an assignable cause, or determine any possible constitutional condition, we found that the patient was subject to attacks of purpura, and that he had had an eruption about the time when he noticed the loss of hearing. This gave us a clue as to what the probable etiology was, and upon the supposition that there was a hæmorrhagic extravasation in the cochlea, or about the auditory nerve, the prognosis was rendered favorable. Without any other treatment than an active saline cathartic, his hearing began to improve on the ninth day from that on which he lost it, and on the twelfth day it was as perfect as it had ever been.

I notice this case because it is one of extreme interest, and because a report of a similar case has never come within my observation.

I am, sir, yours truly,

A. E. PRINCE, M.D.

JACKSONVILLE, Ill.

NEWS ITEMS.

CINCINNATI.

(*From our Special Correspondent.*)

SMALL-POX.—Vaccination has never been so generally practised as during the past few months, since the appearance of variola in our midst. Cases of small-pox have appeared in all parts of the city, but most numerously in the German quarters, where considerable opposition to vaccination is encountered. The most discouraging feature of this ignorant opposition, is that a few so-called physicians are found to encourage it. Nearly three hundred cases have been reported thus far. The law requiring the physician in attendance to give notice thereof to the board of health is very generally and promptly complied with. For neglecting so to do, one prominent physician was recently arrested and fined.

CLINICAL FACILITIES.—As in other affairs, so also in medical education, competition results in benefit to the public. In addition to utilizing the vast amount of material at the city hospital—where all the colleges are represented—the schools all have their own free dispensaries, and one of them a hospital of its own, where clinical lectures are delivered by the faculty. The schools here pride themselves upon their facilities for clinical instruction. In addition to all these features, the Medical College of Ohio has established a lying-in ward in the college building. From this ward two women were taken into the amphitheatre a few weeks ago, and delivered by the professor of obstetrics in the presence of over three hundred students. These two cases happened to occur on the same day, and their peculiarities (one requiring delivery by forceps, the other being a case of prolapse of the funis), rendered that day's clinic a memorable one to the students present.

PITTSBURG.

(*From our Special Correspondent.*)

SMALL-POX.—Owing to the laxness which characterizes the enforcement of the law compelling vaccination—a very efficient law, by the way, which has not in a single instance been vindicated by a prosecution for non-observance of its requirements—we are in the midst of a local epidemic of small-pox, with the Municipal Hospital (for small-pox patients only) filled to repletion, and eighteen to twenty new cases reported daily, besides other cases of varioloid secretly cared for by friends, and not reported to, or sought out by, the health authorities.

CANADA.

(*From our Special Correspondent.*)

THE HAYVERN MURDER CASE has excited our local alienists, and caused a good deal of discussion in the medical journals. Hayvern, a convict, stabbed a fel-

low-prisoner, against whom he had a grudge. The defence raised the plea of insanity, though there were no positive signs of mental disturbance either at the time or subsequently. It is interesting to note, as showing to what lengths some mad-doctors will go, that the principal symptoms relied upon by the defence were, a low temperature, some cutaneous anæsthesia, and sleeplessness. In spite of the strenuous efforts on the part of the Irish Catholics to obtain a reprieve, the law took its course, and the man was executed.

THE NEW CITY HOSPITAL, Hamilton, Ont., is rapidly approaching completion. It consists of two pavilions, with a central administration building, and will accommodate about one hundred patients.

TORONTO GENERAL HOSPITAL. — Under the able management of Dr. O'Reilly, the Toronto General Hospital has become, in many respects, a model one. Certainly in the matter of Xmas decorations it is unrivalled by any institution which we have visited either in this country or in England.

BUREAU OF VITAL STATISTICS.—A deputation, headed by Dr. Fenwick, President of the Canada Medical Association, recently waited on the Dominion Premier to urge the government to the establishment of a Bureau of Vital Statistics.

PUBLIC HEALTH.—Typhoid fever of a mild type still prevails in the cities and towns. Diphtheria is very prevalent in some of the country districts.

LONDON.

(*From our Special Correspondent.*)

THE question that is exciting most interest in professional circles in this country at the present time is that of vivisection. Those of your readers who attended the International Medical Congress will remember what a large share of attention this subject then received and what a strong expression of feeling was elicited on it at the closing general meeting. The aggressive action of a Society for the Protection of Animals from Vivisection has again brought the matter to the front. Perhaps it may be well to put your readers in possession of the history of this question in its legal aspect.

The first attempt to fetter physiologists and pathologists in their vivisectional investigations was made by the Society for the Prevention of Cruelty to Animals, who prosecuted some members of the British Medical Association for conducting experiments at the meeting of that Association, in Norwich, in 1874. The experiments were designed to illustrate the action of absinthe. The prosecution broke down; but this public action gave considerable stimulus to the agitation then rising against vivisection, and in 1875 a Royal Commission was appointed to inquire into the subject. In 1876 "An Act to Amend the Laws Relating to Cruelty of Animals" was introduced into the House of Commons, and after some slight but important amendments was passed through both houses, received the Royal assent, and became the law. The provisions of this Act are in the main these: That no experiment calculated to give pain, or inflict a serious injury, may be performed on any living vertebrate animal, except by a person holding a license from the Home Secretary, and in a licensed place. An anæsthetic must be employed during the whole duration of the experiment, and the animal must be killed before the effects of the anæsthetic have passed off. Should it be essential to the experiment in question that anæsthetics be not used, or that the animal should be allowed to recover from their effects, then a separate and special certificate for this purpose must be obtained. The dog, cat, horse, ass, and mule are specially exempted from vivisectional experiments, unless it is shown that the object of any experiment will be frustrated unless performed on them. The applications for licenses and certificates have to be signed by a president of one of the medical corporations and a professor in medicine, physiology, etc., in some British University.

At the time this Act was passed no decided and united opposition to the whole Act was offered by the medical profession. It is now clear that such would have been the proper course to pursue, and that it would have been far better than any attempts to amend the Act in a manner favorable to experiments. Evidently the effect of this Act depended entirely upon the manner in which it was to be worked, and although the then Secretary of State was free with his protestations that it was not intended by it to throw difficulties in the way of scientific research, it has in practice been so carried out that that has been its sole result. Licenses have been refused and granted only so tardily that the opportunity for carrying out the desired investigations have been lost; special certificates have been refused, and in general the restrictions and annoyances of the law have proved so great that nearly all scientific research through vivisection has been stopped throughout the country. Such men as Lister, Ringer, Ferrier, and Fraser have in this way been prevented from continuing their important investigations in this country.

The intensity of the opposition to this form of scientific research has been well illustrated this week. During the meetings of the Congress the function of the cerebral cortex was discussed in the physiological section, and Prof. Goltz described some experiments on dogs, from which he deduced that the cortex acted as a whole. Dr. Ferrier joined in the discussion and detailed another series of experiments performed on monkeys, which showed that different parts of the cortex cerebri had different junctions. Subsequently about one hundred physiologists met at King's College Laboratory and inspected a dog of Goltz's and two monkeys, on whom Dr. Yeo had operated many months before, one of which was deaf and the other partly paralyzed on one side. Dr. Ferrier spoke and pointed out how the condition of these monkeys supported his views. A summons was taken out against him for this, and counsel attempted to prove that because Dr. Ferrier had examined these monkeys and compared them together, he had conducted an experiment with them which he was not entitled to do without a license, and that he had been a party to keeping the animal alive after the anæsthesia had passed off. The magistrate quickly dismissed the summons. Evidently the case for the prosecution is absurd in the extreme, but its importance lies in the clear indication it gives of the way in which physiologists are hampered in their attempts to unravel the mysteries of life. It is hoped that some action may be taken to induce the Home Secretary to carry out the Act in a more liberal spirit, and not to alter it in some of its details. It is to be hoped that in the United States science will be allowed to work untrammelled by such restrictions; but should occasion arise, never give any quarter to antivivisection agitation, or consent to be burdened in any restrictive act.

BELL'S INDUCTION BALANCE AND THE DETECTION OF BULLETS.—At the Hospital of the University of Pennsylvania, on Dec. 21, Prof. Agnew gave Mr. Gleason, of Boston, an opportunity to demonstrate the operation of Bell's Induction Balance (see p. 46) upon patients, in whom bullets had been imbedded for years. The apparatus was the same as was used in the case of President Garfield, with some added improvements. The experiment was conducted before the medical class, and in the presence of a number of interested medical men. In one case the bullet had been received nineteen years

ago, and was supposed to be lodged somewhere in the arm. After explaining the *modus operandi* of the apparatus, a careful search was made over the patient's whole arm and shoulder, but entirely without success. Several times Mr. Gleason exclaimed, "There, there it is!" but after all, had to give it up.

The second patient was a negro, who had been shot in the left buttoch. In his case also, the apparatus failed to give any information. It seemed to show something after Drs. Agnew and John Ashhurst, Jr., had found a spot, when they felt with their fingers what they thought might be an encysted ball; but even then the coidence was too doubtful and inconsistent to be of any value. Besides the disks, the insulated needle was used, thrust deep down to where Dr. Agnew thought he felt the ball, but even this brought no response.

The experiment proved of no use as an aid to determining the location of the missiles in these two cases; though it was easy to hear the modification of tone in the telephone when the disks were passed over Mr. Gleason's cheek, while he held a bullet in his mouth, or when the needle was thrust against a bullet buried buried in a piece of raw beef. In a case under the care of Dr. Hamilton, the apparatus detected a ball in the anterior wall of the chest, but that was very close to the surface.

After the conclusion of the experiments, Dr. Agnew made an exploratory incision back of the trochanter major, which disclosed that the bullet was not there.

CAUSE OF THE IMPURE WATER IN BOSTON.—Prof. Ira Remsen, according to the *Boston Medical and Surgical Journal*, December 1, has found on the screen at the effluent gate of Farm Pond, one of the water suppliers of Boston, moss-like matter having the same peculiar nauseous smell as the water in Boston, and which, on investigation, proved to be a fresh-water sponge, the *spongilla fluviatilis*. It is probable that this decaying substance is the principal cause of the trouble.

THE BOSTON MEDICAL LIBRARY ASSOCIATION has issued an appeal for further subscriptions, being desirous of raising fifteen thousand dollars for the purpose of cancelling the entire debt, making some pressing and long-neglected repairs, and having a small fund for binding and for buying new books as soon as issued. The appeal is signed by Dr. Oliver Wendell Holmes and others, and will doubtless receive a liberal response from the citizens of Boston, who are well known for the liberal manner in which they foster literary and scientific objects.

NEW YORK STATE BOARD OF HEALTH.—The regular quarterly meeting of the New York State Health Board was recently held at Albany. The means for preventing poisonous adulterations of confectionery were discussed. A committee was appointed to represent the Board at the meeting of the Public Health Association. Various plans, having for their object the supply of pure vaccine virus, were discussed. The committee on the Hunter's Point odors reported that the great majority of the manufacturers have taken measures to abate the nuisances, in accordance with the Governor's proclamation, and that the effluvia are by no means so offensive as they have hitherto been. Measures will be promptly taken to close a few refineries, which are still the source of harmful emanations.

IOWA STATE MEDICAL SOCIETY.—The thirtieth annual meeting of this Society will be held at Des Moines on January 25, at 10 A.M., and will continue three days. The annual address will be delivered by T. J. Caldwell, M.D., President of the Society. A large number of papers have been promised for the meeting.

POST-GRADUATE INSTRUCTION IN PHILADELPHIA.—At the University of Pennsylvania there will be given, during the spring of 1882, a course of instruction by clinical methods, intended for practitioners and recent graduates. The plan includes teaching upon general medicine, nervous diseases, otology, dermatology, ophthalmoscopy, gynæcology, operative surgery, and venereal diseases, by Profs. Pepper, Wood, Strawbridge, and Duhring, and Drs. Bruen, Risley, Baer, and White. The object of this course will be to supplement the regular instruction given during the winter months, and, more especially, to afford physicians desiring to extend their acquantance with special branches, an opportunity of doing so in a most practical manner, and at a season when they can, perhaps, best spare the time.

As there has been abundant evidence of the need and desire for such instruction among the profession in all parts of the country, it is hoped that the general effort which is being made in this direction, not only here, but in several parts of the country, may deserve and meet with success.

THE MEDICAL SOCIETY OF VIRGINIA held its twelfth annual session at Old Point Comfort, Va., on October 10th and 11th. The following officers were elected for the ensuing year: *President*, Dr. G. Wm. Semple, of Hampton; *Vice-Presidents*, Drs. W. L. Robinson, of Danville; W. D. Cooper, of Morrisville; J. S. Apperson, of Town House; Wm. B. Gray, of Richmond; T. James Taylor, of Walton, and S. B. Morrison, of Brownsburg; *Recording Secretary and Treasurer*, Dr. Landon B. Edwards, of Richmond.

The next meeting of the Society will be held at Fauquier White Sulphur Springs, Va.

NEXT INTERNATIONAL CONGRESS.—A meeting of 250 physicians was held at Copenhagen on Nov. 28, at which a resolution was adopted approving the proposal to hold the next International Medical Congress, in 1884, at Copenhagen, and proffering a cordial welcome by the Danish medical profession to their brethren from foreign countries.

THE UNITED STATES PHARMACOPŒIA.—The revision of the *Pharmacopœia*, we are informed, is nearly completed. The work will make a duodecimo volume of from 400 to 450 pages. The mode of issuing it must be very soon considered and decided. The copyright will be disposed of, no doubt, in accordance with the instructions, on the best terms obtainable. The manner of inviting proposals for the publication of the work has not yet been determined. It is probable, however, that those who think of competing for the copyright may obtain the information desired by applying to the chairman of the "Committee of Revision," Mr. Charles Rice, Bellevue Hospital, New York.

MAURY COUNTY MEDICAL SOCIETY.—This society has recently organized at Columbia, Tenn., with a large membership, by the election of the following officers: President, Dr. J. H. Wilkes; Vice-President, Dr. Robert Pillow; Secretary, Dr. John Bowen; Treasurer, Dr. J. E. Dixon; Censors, Dr. Wm. B. Harrison, J. Spencer Hill, and C. W. Winn.

FEMALE MEDICAL STUDENTS IN PARIS.—Great consternation prevails among the students in Paris at the decree of the Minister of the Interior, which, it is said, will shortly be published, according to lady medical students the right to compete for the House Surgeonships, hitherto denied to them. The agitation seems to be principally on the ground that the men can no longer have the house to themselves, but will be restrained by the presence of ladies.

SMALL-POX.—Information received from various parts of the country indicate the wide-spread and rapidly increasing prevalence of small-pox. In the State of Michigan we learn that it is reported at Bay City, Detroit, Grand Rapids, Kalamazoo, South Haven, and Union City. The one new case at Grand Rapids was believed to have been brought from North Carolina. The case at Union City was brought from Cincinnati. At Kalamazoo the disease was probably contracted by sorting paper-rags. At all of the six localities from which small-pox is reported, it is believed to be under the control of the local health authorities.

DEODORIZING IODOFORM.—M. Catillon, in the *Gazette Hebd. de Méd. et de Chir.*, Nov. 4, 1881, describes a successful mode of removing the repulsive odor of iodoform. It suffices to add to the iodoform, in a bottle in which it is preserved, some fragment of Tonquin bean. The odor then becomes no longer recognizable, and recalls that of bitter almonds. It lasts for many days, even when the iodoform is withdrawn from the bottle and exposed to the open air.

RUPTURE OF THE BLADDER.—The *Lancet* for November 12, 1881, contains an interesting article, mainly historical, on the subject of rupture of the bladder.

Among the predisposing causes of this injury alcohol is mentioned as producing at the same time a rapid secretion of urine and a condition of diminished sensibility of the mucous membrane, both of which tend to produce a condition of distention without which rupture is impossible. It is also shown that the distended bladder may be ruptured through violent contractions of the abdominal muscles.

LITERARY NOTES.—*Vratchebrinya Vedomosti*, a Russian medical journal, publishes a translation of the able address of Dr. Billings, before the late International Medical Congress.

It is stated that the Transactions of the late International Medical Congress, in four royal 8vo volumes, of 600 pages each, are ready for delivery to members. Another proof, if one were wanting, of the ability and unceasing energy of the Hon. Secretary-General, Sir William MacCormac. Members desirous of obtaining their copies should apply immediately to Mr. Kolckmann, No. 2 Langham Place, London, W., enclosing a remittance of five shillings to cover postage. Copies may be obtained by non-members at £2 2*s.*, or separate volumes at 10*s.* 6*d.* each. Volume I. contains List of Members, General Meetings, General Addresses, Museum, Anatomy, Physiology, Pathology, Materia Medica, and Pharmacology. Vol. II., Medicine, Military Surgery, and Medicine Surgery. Vol. III., Ophthalmology, Mental Diseases, Diseases of the Skin, Diseases of the Throat, Diseases of the Ear, Diseases of the Teeth. Vol. IV., Diseases of Children, Obstetric Medicine and Surgery, State Medicine. These volumes are in paper covers, but may also be had in fine bindings at an additional cost, ranging from £1 10*s.* per volume for best polished morocco, with bronze Congress medal in the front cover, to half calf at 4*s.* 6*d.*

Gray's *Anatomy* has been translated into the Chinese language, and published in six volumes at Foochow.

Fordyce Barker's *Puerperal Diseases*, and T. A. Emmett's work on *Gynæcology* have been translated into the Dutch, and Dr. Costa's *Diagnosis* into the German language.

APPOINTMENTS.—The Board of Trustees of the University of Louisville, have appointed Dr. Theophilus Parvin, of Indianapolis, to the chair of Obstetrics and Diseases of Women, made vacant by the death of Dr. Crowe. The university may be congratulated on the addition to its faculty of so distinguished a gynæcologist, and so eminent a teacher as Prof. Parvin.

The Faculty of the College of Physicians and Surgeons, of Baltimore, Md., have called Dr. Richard Gundry, to occupy the chair of Materia Medica, Therapeutics, and Mental Diseases.

Dr. Lewis S. McMurtry, of Danville, Ky., has accepted the chair of Anatomy in the Kentucky School of Medicine, in place of Dr. Cook, who has removed to San Francisco, Cal. Dr. McMurtry will remove to Louisville.

Dr. J. Forsyth Meigs has resigned the position of Visiting Physician to the Pennsylvania Hospital, and Dr. Arthur V. Meigs has been elected to fill the vacancy.

Dr. Louis Elsberg, of New York, has been elected Professor of Laryngology and Diseases of the Throat in Dartmouth Medical College, and he has resigned the clinical lectureship on the same subjects, which he held in the University of the City of New York.

PERSONALS.—The Royal Society of London have conferred the Copley medal, the highest distinction in their power, on M. Würtz, the eminent French chemist, for his valuable contribution to science.

M. Pasteur has been elected to the seat in the French Academy made vacant by the death of M. Littré.

It is proposed to place a marble bust of Mr. Erichson in University College, London, as a mark of respect for his long connection with, and great services to, the School of Medicine of that College.

Virchow has been made an honorary member of the Universities of Bologna and Kasan, as well as of the College of Physicians in Vienna and the German Society for Public Hygiene in Berlin. Dr. B. F. Leonard has been appointed Professor of Physiology; Dr. W. R. Monroe, Professor of Materia Medica and Therapeutics; Dr. H. L. Byrd, Professor of Obstetrics and Diseases of Women and Children; Dr. H. Froehling, Professor of Chemistry, Toxicology, and Medical Jurisprudence in the Baltimore Medical College.

Dr. J. R. Chadwick has been appointed Instructor in Diseases of Women, and Dr. E. H. Bradford Special Instructor in Orthopœdics in the Harvard School.

CONSIDERABLE currency has been given by the medical and lay papers to the story that immediately after the assassination of President Garfield Professor Gross volunteered his professional services at the White House, and that they were declined. Even at this late date we find the report still obtaining currency through the press, and we deem it due to the distinguished surgeon in question to say that we have the best authority for stating that the story is utterly without foundation.

DIED, at Hastings-on-the-Hudson, on January 4, JOHN W. DRAPER, M.D. Dr. Draper was born at St. Helena, near Liverpool, England, on May 5, 1811. He received his early education in England, and came to this country in 1833, where he continued his chemical and medical studies, commenced at the University of London, in the medical department of the University of Pennsylvania, where he took the degree of M.D. in 1836. Soon after graduation he was appointed Professor of Chemistry, Natural Philosophy, and Physiology in the Hampden-Sidney College, Virginia. In 1839 he was called to the chair of Chemistry and Natural History in the University of New York, and in 1841 he was appointed Professor of Chemistry in the University Medical College, where he was long President of both the scientific and medical departments.

Dr. Draper's numerous and valuable experimental researches were published in the *American Journal of the Medical Sciences*, *London and Edinburgh Philosophical Journal*, and the *American Journal of Science and Arts*. He was likewise the author of many literary

works and reviews: *A Treatise on the Forces which Produce the Organization of Plants* (1844); *A Text-Book on Chemistry* (1846); *A Text-Book on Natural Philosophy* (1847); and one on *Human Physiology* (1856), which passed through numerous editions. His *History of the Intellectual Development of Europe* appeared in 1852, and was almost immediately afterwards republished in England, and translated into French, German, Italian, Polish, and Russian, and has passed through many editions in this country. In some respects, his most important work was the *Conflict between Science and Religion*, which attracted great attention, and was translated into all the principal languages. He was also the author of *A History of the American Civil War*, and *Thoughts on the Future Civil Policy of America*.

In 1874, the American Academy of Science conferred the Rumford medal, the highest distinction in their gift, on Prof. Draper, for his researches on *Radiant Matter*.

Dr. Draper was one of the most eminent scientists and philosophical thinkers our country has produced, and history will probably accord to him high and enduring fame.

Dr. Draper had two sons, both distinguished in science—Prof. Henry Draper, the eminent spectroscopist, and Prof. Daniel Draper, who is well known as a meteorologist.

——, on November 25, Prof. WILHELM BUSCH, in the fifty-fifth year of his age. Prof. Busch was a student and assistant of Johannes Müller, and in 1848 took part in the Schleswig-Holstein war, where his aptitude for surgery was developed under the guidance of Langenbeck. In 1855 he was elected Professor of Surgery in the University of Bonn, and was Surgeon-General of the Prussian army in 1866–70. His earliest works related to comparative anatomy, and the later to surgery, in which his writings on the subjects of the influence of the mechanism in inflammation and dislocation, the mechanism of strangulated hernia, and gun-shot wounds are the best known. Prof. Busch recently received the great Cross of the House of Hohenzollern, with an autograph letter from the Emperor, in gratitude for a successful operation performed on the Empress.

The death of Dr. NIKOLAUS PIROGOFF is announced by telegram from St. Petersburg. He was Professor of Surgery to the Medico-Chirurgical Academy in St. Petersburg, and a member of the consulting staff of several hospitals in that city. In 1840, he brought out a valuable treatise on the division of the tendo-Achillis in orthopædic surgery. He also wrote on cholera, on the surgery of the arterial trunks and of fasciæ, and on the medical aspects of the Caucasus, and on topographical anatomy. His work on this last subject forms a fine atlas of anatomy, as illustrated by frozen sections. It is, however, with military surgery that his name will ever be most closely associated. He is the medical historian of the Crimean and Circassian campaigns; and also wrote a report on the permanent and improvised military hospitals in Germany and Alsace-Lorraine during the war of 1870. The late Professor is probably best known to Englishmen in association with one of the numerous methods of partial amputation of the foot. —*British Med. Journ.*, Dec. 10, 1881.

NOTES AND QUERIES.

PENNSYLVANIA RAILROAD COMPANY'S INSTRUCTIONS FOR EXAMINATION OF EMPLOYES AS TO VISION, COLOR-BLINDNESS, AND HEARING.

MR. FRANK THOMSON, General Manager of the Pennsylvania Railroad Company, has issued the following instructions, under which examinations will be made on each division of the road, as soon as practicable, of all employés in positions where they are required to use or be governed by signals. Persons will not be appointed to such positions until they have satisfactorily passed similar examinations. Employés failing to come up to the required standard, will have the privilege of a professional examination by experts designated by the General Manager.

Instructions for Examination as to Vision, Color-Blindness, and Hearing.—The examination will be made by, or under the direction of the Division Superintendent, and will be as to vision, color sense, and hearing, and the following apparatus will be used:

1. A card or sheet of large letters for testing distant sight. 2. A book or card of print for testing sight at a short distance. 3. An adjustable frame for supporting the print to be read, with a graduated rod attached for measuring the distance from the eye while reading. 4. A spectacle frame for obstructing the vision of either eye while testing the other. 5. An assortment of colored yarns for testing the sense of color. 6. A watch with a loud tick for testing the hearing. 7. A book or set of blanks for recording the observations. 8. A copy of an approved work on "Color-Blindness."

Acuteness of Vision.—For distant vision, place the test card in a good light twenty feet distant, and ascertain for each eye separately, the smallest letters that can be read distinctly, and record the same by the number of that series on the card.

Range of Vision.—For near vision ascertain the least number of inches at which type D = 0.5 or 1½, can be read with each eye and record the result.

Field of Vision.—Let the examiner stand in front of the examined at a distance of three feet, and directing the examined to fix his eyes on the right eye of the examiner and keep them so fixed, let the examiner extend his arms laterally, and opening and shutting his hands, let him by questions satisfy himself that his hands are seen by the examined, without changing the direction of the eyes; recording the result as good, or defective, as the case may be.

Color Sense.—Three test-skeins—A, light green; B, rose; C, red;—will be used with the colored yarns attached to the stick; of the latter there are forty tints, numbered from 1 to 40, and arranged in three sets—a, b, and c—of which the odd numbers correspond to the colors of the test-skeins, whilst the even numbers are different or "confusion colors."

The first set is to test for color-blindness; the second to determine whether it be red or green blindness, and the third to confirm the opinion formed from the first or second test.

Place the test-skein A at a distance of not less than three feet, and without naming the color, direct the person examined to name the color, and to select from the first twenty tints, or set (a) of the yarns on the stick, ten tints of the same color as skein A, stating that they do not match, but are different shades of the same color. Record the number of the tints so selected. Do the same with skeins B and C, using for B the tints from 21 to 30, and for C the tints from 31 to 40. If the odd numbers are selected readily, the examination may be gone over very quickly.

When color-blindness is detected, any one of the even numbers or "confusion colors" may be used as a test-skein, and the man may be directed to select similar tints, when he will most probably choose odd numbers, which should be recorded, stating the number on the stick of the confusion color used for a test, and then giving the numbers chosen to match it.

Then a soiled *white* flag should be shown, and the man be directed to select tints to match it, which should be recorded; next a *green*, and finally a *red* flag.

All of the particulars are to be recorded as the examination proceeds, not leaving it to memory. Use the numbers in recording. The letters indicating the set need not be used. Note whether the selection is prompt or hesitating by a distinct mark after the proper word on the blank form. When deficient color sense is discovered, and variations in the mode of testing are made by the examiner or examined, they should be noted under remarks, or on a separate sheet to be referred to, if the blank has not room enough.

Hearing.—Note the number of feet or inches distant from each ear at which a watch, having a loud tick, is heard distinctly, using a watch without tick, or a stop watch, to detect any supposed deception; and the number of feet at which ordinary conversation is heard.

Explanations.—The test-card contains letters, numbered from 20 (xx) or D = 6. to 200 (cc) or D = 60. Those measuring three-eighths of an inch, and numbered 20 (xx) or D = 6. are such as a good eye of ordinary power sees distinctly twenty feet or six metres distant. If a man sees distinctly only those marked C (or 100), his acuteness of vision, V, is equal to $\frac{20}{100}$ or $\frac{1}{5}$. If he sees XX (or 20). then V is equal to $\frac{20}{20}$, or 1, and his sight is up to full standard, This mode of statement indicates the relative value of the sight examined, and should be used in the records. If one eye is $\frac{20}{20}$, or 1, and the other not less than $\frac{20}{50}$, or $\frac{1}{2\frac{1}{2}}$, with or without glasses, the sight may be considered satisfactory.

The power of discerning small objects at the reading distance is tested by the small print, and good sight may be assumed if one eye can see at twenty inches the matter marked 1½ or D = 0.5, whilst the other distinguishes not less than 4½ or D = 1.5. The small print should then be brought to the point of nearest vision for each eye, and that point mentioned in inches. A good eye should be able to read No. 1½ at twenty inches, and have a *range of vision* up to ten inches.

The color test will indicate whether the man is deficient in color sense. The colors are arranged in three sets, one of 20 and two of 10 each—the odd numbers are the colors similar to the test-skeins, and the even numbers are the "confusion colors," or those which the color-blind will be likely to select to match the sample skeins or colors shown him. The first 20 (a), numbered from 1 to 20, have green tints for the odd numbers or test-colors. In the second (b), 21 to 30, the test-colors are rose or purple, a combination of red and blue; and the third (c), 31 to 40, they are red. Ordinarily the test will be with each set separately, but the whole 40 may be employed on any test-skein. Anything but *green* matched with *green* indicates a defect in the color sense for which use set (a).

The test with the second set indicates whether red or green blindness exists. The odd numbers from 21 to 30 are purple. If either of these is matched with test-skein B, nothing is indicated, as they must appear alike to a color-blind person; but if blue is chosen, red blindness is indicated, and if green, then green blindness is established.

The third set (c) is scarcely needed, but may be used in confirmation of, or in connection with, the last, as to red or green defect.

When the numbers of the tints selected are recorded in the proper blank, color-blindness will be indicated in those instances where even numbers appear, and suspicions will arise where numbers beyond 20 are used with test-skein A, and under 21 or beyond 30 with B, and below 31, with C.

Further tests should be made of those found to be color-blind with the usual signal flags, requesting them to name each color shown singly, and to match the colors of them from the tints on the stick, and with colored lamps; and finally to state what they understand them to mean as signals.

It will be well not to dwell on the examination of a man found to be defective in color sense or in vision, but to pass over each examination with the same general care, and afterwards send for those giving indications of defects, to come in singly for fuller examination. The examination should be private as far as practicable, especially excluding persons who are to be subsequently examined.

Inability to name color accurately, or to distinguish nicely as to difference in tint, is not to be taken as an evidence of color-blindness.

In testing as to hearing, if a person who has a good ear hears the watch used at five feet distant, and the person examined hears it only at one foot, his hearing would be 1-5, and may be recorded in fractions. Conversation in an ordinary tone should be heard at ten feet.

It should be understood that all employés examined, failing to come up to the requirements of the above standard, shall be accorded the benefit of a professional examination. When acuteness of vision is below the standard adopted, it may be possible to restore full vision by proper glasses, when it is due to optical defects, known as near-sight, far-sight, or astigmatism, or by other medical or surgical treatment, and useful men may then be retained in the company's service.

TO THE EDITOR OF THE MEDICAL NEWS.

SIR:—I have read with interest the editorial on "Free-trade in Medicine," in your issue of January 7, and was glad to learn of the pleasant way in which an English contemporary speaks of our native medical literature. I cordially agree with your statement that direct control of medical education by political boards is at least at present not desirable, but that "flagrant irregularities" should be corrected. I am rather surprised, however, at your conclusion that our "free development and successful progress" are owing "to our system of free-trade in medicine." With the highest admiration for the achievements of American physicians, and for their justly esteemed contributions to medical literature, I am yet totally unable to see in what manner the so-called "free-trade" which exists here has stimulated their labors or improved the character of their productions, and, therefore, how your conclusion is justified by the premises.

It is true that we have been successful, and, as a profession, have much to be proud of, but it has been *in spite* of many serious hindrances and mortifying obstructions, due, it appears to me, largely, if not altogether, to this very lack of restriction which, as we all know only too well, has permitted thousands of incompetent men to enroll themselves in our ranks, and to compel us to bear the burden and the shame of their ignorance. This, to my mind, seems the direct outcome of our "free-trade," which to a greater or less extent is responsible for the absence of preliminary training, the short terms of study, the easily gained diplomas—in brief, the defective medical education—which, I am glad to say, is rapidly ceasing to be a source of discredit and of opprobrium to the profession in America. Very respectfully,

J. WILLIAM WHITE.

PHILADELPHIA, Jan. 10, 1882.

[Our correspondent appears to have mistaken the purport of the editorial to which he refers, viz., the question of governmental control of medical education. We did not assume to analyze the causes of our "successful progress," but simply to call attention to a point which had been noted by an English contemporary. While we have no doubt that our medical progress has been impeded by the causes our correspondent mentions, that was not a point under consideration. With our political system, we believe it is unquestionably better for medical education not to be made the subject of political control, and in the editorial referred to, while we expressed distinct approval of "appropriate legislation," we equally distinctly expressed disapproval of paternal legislation, which, history teaches, even under the best civil service, ultimately hinders the advance of knowledge.—ED.]

TRANSACTIONS OF THE PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THE Pathological Society of Philadelphia desires to sell the surplus volumes of its transactions, and offers them at sixty cents per volume, postage free. Copies may be obtained of the Treasurer, Dr. French, 1423 Walnut Street, Philadelphia.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 2, 1881, TO JANUARY 3, 1882.

MURRAY, ROBERT, *Colonel and Surgeon, Medical Director, Military Division of the Missouri.*—The leave of absence granted him in S. O. 100, October 5, 1881, Military Division of the Missouri, is extended two months.—*S. O. 272, A. G. O., December 2, 1881.*

SUMMERS, JOHN E., *Lieutenant-Colonel and Surgeon, Medical Director, Department of the Platte.*—The leave of absence granted him in Par. 6, S. O. 123, Department of the Platte, December 1, 1881, is extended one month.—*S. O. 135, Military Division of the Missouri, December 28, 1881.*

ALEXANDER, R. H., *Major and Surgeon.*—The leave of absence granted him in S. O. 215, September 19, 1881, from A. G. O., is extended one month.—*S. O. 285, A. G. O., December 17, 1881.*

MCCLELLAN, ELY, *Major and Surgeon.*—Relieved from duty at Fort McHenry, Md., to proceed to Fort Trumbull, Conn., and relieve Assistant Surgeon, W. H. King.—*S. O. 224, Department of the East, December 15, 1881.*

KING, W. H., *Captain and Assistant Surgeon.*—When relieved by Surgeon McClelland, to repair to Fort McHenry, Md., and report for duty at that post.—*S. O. 224 c. s., Department of the East.*

HAVARD, V., *Captain and Assistant Surgeon.*—Now *en route* from Fort Davis to San Antonio, Texas, assigned to temporary duty at Headquarters Department of Texas, and to report to the Medical Director for instructions.—*S. O. 154, Department of Texas, December 12, 1881.*

PERLEY, H. O., *Captain and Assistant Surgeon.*—Having reported in person at these headquarters, will report to the commanding officer, Fort Columbus, N. Y. H., for duty, as assistant to the post surgeon, and attending surgeon at these headquarters.—*S. O. 224 c. s., Department of the East.*

RAYMOND, HENRY I., *First Lieutenant and Assistant Surgeon.*—Relieved, temporarily, from duty at Alcatraz Island, Cal., and to report to the commanding officer of the Presidio of San Francisco for duty at that post.—*S. O. 214, Military Division of the Pacific and Department of California, December 9, 1881.*

MADDOX, THOMAS J. C., *First Lieutenant and Assistant Surgeon.*—Having completed the duties assigned him under S. O. 248, November 3, 1881, from A. G. O., will report in person to the Surgeon-General, U. S. Army.—*S. O. 238, A. G. O., December 15, 1881.*

THE MEDICAL NEWS will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the "News" should be addressed to No. 1004 Walnut Street, Philadelphia.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON SOME OF

THE ABUSES OF THE DRAINAGE-TUBE.

BY STEPHEN SMITH, A.M., M.D.,

SURGEON TO BELLEVUE AND ST. VINCENT HOSPITALS, NEW YORK.

GENTLEMEN: The drainage-tube has become one of the constant appliances in the treatment of wounds, abscesses, and tissues undergoing suppurative inflammation. In passing through the surgical wards of an hospital, one can but be struck with the frequency with which they are met. They protrude from every abscess, in whatever stage of healing it may be; from wounds of every grade; from open joints; from compound fractures; from areas of cellulitis. If we inquire as to the reasons for using them under these varying conditions and circumstances, we learn that they are placed between the surfaces of the fresh wound, to prevent the accumulation of septic fluids; that they are left in abscess cavities to drain away fluids and to admit the washing out of the cavities; that they are passed through inflamed cellular tissue to drain off pus, and allow the injection of disinfectants.

If we examine critically as to the conditions under which the tube was first applied, we shall find that in many instances, had the wound been properly treated, no septic fluid could have accumulated, and that the tube was the only thing which made the collection of such fluid possible. If, again, we examine individual cases under treatment, we shall find that, in a surprisingly large number, the drainage-tube has not only long ceased to drain away septic matters, but has itself become a source of irritation, and is perhaps the only obstacle to the rapid healing of the wound. The drainage-tube, therefore, though an instrument of great value when properly employed, is undoubtedly capable of doing much mischief when used without proper discrimination. It is of great importance to commence its use with correct ideas as to the precise circumstances and conditions to which it is adapted. In the first place, let me say that the drainage-tube can serve but two useful purposes, viz., 1, as a drain of fluids from a cavity; and, 2, as a medium for the injection of fluids into a cavity. It should be added that it may act in this twofold capacity in a single case. When, however, it ceases to be useful in one or the other of these functions, it has ceased to be useful at all, and its further employment is harmful. Now let us apply these principles to practice in the cases which have passed under your observation in this hospital.

In incised wounds, the tube should never be used when the two surfaces can be brought accurately together and maintained in apposition. This may seem a needless piece of advice, and yet I do not doubt that you have seen it used in just such cases, and perhaps many times. In the removal of tumors large flaps are often formed, and as they are raised up it seems quite impossible to bring the opposing surfaces accurately together; and yet with a little care they can be adjusted, and with careful padding maintained in apposition for the brief period necessary to their union. It is simple carelessness and negligence on the part of the surgeon who allows the surfaces to separate so that a dêpot is formed for the accumulation of fluids, which necessitates the use of the tube. And I am quite sure that the popularity of the drainage-tube is such with many surgeons that they would place it between the surfaces of the wound without even raising the question as to their ability to secure immediate union by properly adjusting the external dressings. But the difference in the time of healing wounds capable of accurate adjustment, treated with and without the tube, is very great; in the former case, the tube acts as an irritant, and the wound may not, at the best, heal in several weeks, while in the latter, union may be perfected in forty-eight hours.

To thrust a drainage-tube into such a wound and maintain it there for the purposes of drainage and the injection of disinfecting fluids, is, to say the least, very improper practice. Consider, therefore, in every incised wound, whether you cannot so adjust and maintain the opposed surfaces that no open space can exist.

In amputation wounds the tube is now generally thrust into the bottom of the wound, and some surgeons allow it to pass completely through the base of the wound. There it is often maintained in position long after all danger has passed of the accumulation of fluids, as an irritant, preventing the final closure of the wound. Now in the larger number of amputations the flaps should be so formed as to place the angle of separation at the most dependent part. This position admits of the most perfect drainage of the wound without the interposition of a tube, or tent, or other irritating body. But even if a tube is deemed immediately necessary, it should only penetrate to the bone, where a cavity may exist if the flaps are not well supported. If the flaps are made antero-posteriorly, the lines of separation being transversely, the tendency to the accumulation of fluid within the flaps is increased. In this case the tube may prove useful for a few days; but it is usually possible to place the stump in such position that the drainage is direct. If that is done, the tube is either useless or needs to be employed but for a day or two. It should also be borne in mind that an amputation wound may heal without suppuration if the flaps are properly supported at every point, and no foreign substance intervenes.

In abscesses unconnected with diseased bone, the drainage-tube is frequently, if not generally, used much too long. The usual method of treating cold abscesses is to puncture, introduce the drainage-tube, and daily throw carbolized injections into the cavity through the tube, which is allowed to remain sometimes for months. The rule should be to dispense with the tube as soon as we are satisfied that the cavity is free from septic matters, which may follow the first injection. Then all that is required is apposition of the opposing surfaces, and union of the granulations will rapidly take place. Apposition is secured by uniform external compression. In many cases these abscesses may be perfectly obliterated in five or six days by the following method: Puncture the sac and evacuate the contents, introduce the tube, and holding the edges of the puncture firmly about it, inject a carbolic solution three per cent. strength until the cavity is over-distended; allow the fluid to escape, and inject again until the escaping fluid is colorless; now remove the tube, carefully adjust wet carbolized sponges, squeezed as dry as possible, over the entire surface of the abscesses, and bandage them firmly in position. The effect is to cleanse the cavity of all septic matters, and then to press the walls of the abscess gently and firmly together. Union of the two walls is often completed at a single dressing, retained

four or five days. If the abscess is inflamed, the tube is often useful in securing drainage from recesses which otherwise would retain decomposing fluids. But there comes a limit to the time when the tube is useful for drainage, and should only be employed to throw injections into the deeper parts which would not be reached by the ordinary force of the syringe.

Through-and-through drainage has latterly been recommended and practised in open wounds, suppurative cellulitis, suppurating joint cavities, compound fractures, etc. This method of drainage is often of very doubtful utility, and is certainly liable to great abuses. The alleged object of this treatment of wounds is to prevent inflammation by the direct antiphlogistic properties of carbolic acid applied to the surface of the wound. The tube, having fenestræ cut in it, is therefore passed completely through the wound and out at the opposite side, and the treatment consists in injecting a solution of carbolic acid through the tube several times daily, thus constantly medicating the internal surfaces of the wound by the injected fluid. It matters little on what theory this application of carbolic acid is made, for it is very liable to be abused when employed by means of through-and-through drainage-tubes. Carbolic acid can do no possible good when frequently applied to a fresh, healthy wound, but must prove an irritant which will prevent union. The drainage-tube passed through the deeper parts of such a wound is a source of irritation simply, without any other function. It is alleged that there are cavities in the deeper parts of wounds which must be drained and washed out; but the very existence of such cavities in fresh wounds too often proves that the requisite adjustment and compression of the flap or flaps was not made. The early passage of a drainage-tube through the wound of a compound fracture, and out at some unbroken part, in order to prevent inflammation, is productive of more harm than good. It may convert, when performed early, a compound fracture, which by proper means might have been made a simple fracture, into one of the most intractable wounds which we have to treat. And even if tubes are passed during the suppurative stage, it is questionable if they are nearly as efficacious as incisions into the suppurating cellular tissue, followed by injections of carbolic solutions. In suppurating cellulitis, it is advised to pass the drainage-tube through the area involved and out at a point beyond; through this perforated tube the injections are thrown for the purpose of disinfecting the cellular tissue and draining away accumulating pus. In general, drainage-tubes do much more harm than good in this disease. They add a new cause of irritation, and as they are frequently continued for a long time, they not only aggravate the acute stage of the affection, but prolong the period of recovery. The only instance in which through-and-through drainage can be useful in cellulitis is where there is a large cavity of pus which cannot be drained except by a counter-opening; and it is doubtful if this method is superior to the old one of a direct counter opening.

Many other examples might be added of the improper employment of the drainage-tubes; but they will be apparent on giving you a rule for its use. As a rule, then, use the drainage-tube only to remove from cavities fluids liable to undergo putrefactive changes if retained, and to cleanse such cavities by the injection of disinfectants. There are abundant uses of the tube for these purposes. Wounds will frequently allow depôts of purulent matters to form in spite of all our care, and these must be early drained and cleansed. Abscesses are often so placed that we cannot compress them after evacuation, but must drain and disinfect their cavities until they heal by the slow contraction of their granulations. Cellulitis may result in the formation of large collections of putrid fluids, which can best be removed by the tubes, through which the cavity can only be effectually cleansed. Inflamed joints present natural cavities which may require cleansing and drainage.

The impression which I wish to leave upon your minds is this, viz.: that the drainage-tube has certain definite uses, and when so used is of great practical value, but that it is very liable to abuse by a failure to discriminate as to the cases to which it is adapted, and the time in any given case when its usefulness ceases.

ON THE

INFECTIOUS CAUSES OF INFLAMMATION.

Two Lectures delivered at the Pathological Institute of the University of Leipsic, December 8 and 9, 1881.

BY PROF. JULIUS COHNHEIM.

LECTURE I.

(Reported for the MEDICAL NEWS, by special permission of the Author, by Dr. WALTER MENDELSON.)

GENTLEMEN: If we now turn to infection as a cause of inflammation, those diseases which have long passed under the name of *infectious* will first occupy our attention. Without entering into an elaborate definition, I would merely say that, by infectious diseases, we understand such as are caused by the action of a poison, a virus—a virus which is not present at all times and in every place, but is produced only by certain persons who are themselves the subjects of the disease—in certain localities or at certain times or seasons. Two forms of the poison are more especially distinguished, the *contagious* and the *miasmatic*. Under the former is understood a virus which develops in individuals already ill—the *endogenous* form of Pettenkofer; while by miasma we understand one which originates in the soil, in the atmosphere, or in the water, that is, always outside of a morbid body, *i. e.*, exogenously. Contagious diseases, therefore, can only be transmitted from one person to another or from an animal to man, or *vice versa;* while miasmatic diseases appear in individuals who have never been brought in contact with others similarly affected. Measles, scarlatina, whooping-cough, small-pox, exanthematic typhus, relapsing fever, syphilis—all these are purely contagious diseases, while the malarial fevers, and, above all, the intermittent, are types of purely miasmatic disorders. Measles may be acquired in any locality only by coming in contact with one already ill of that disease; while, on the other hand, you may safely associate with a person having intermittent fever, and yet get fever and ague in a malarial district without ever having as much as seen any one ill of it.

There is a class of infectious diseases, however, which cannot be placed under either of these headings. In anthrax (splenic fever), we are familiar with a disorder most markedly contagious, and which never occurs in man unless transferred to him from animals. In animals, however, we find the disease appearing without their ever having come in contact with infected individuals, the poison originating undoubtedly in a certain locality in the soil, apparently spontaneously, and therefore to be classed as a miasma. Then there is a series of diseases which spread neither by direct personal contact nor from fomites, and yet which never appear in a place without a case having been previously introduced from without. Never yet has cholera broken out in a city without a case having been brought in first, nor has any one ever yet got cholera by direct infection from one ill of it. This class of diseases, to which I may also add typhoid fever, yellow fever, and epidemic dysentery, is called *miasmatic-contagious*, a designation which in itself shows that the generally accepted classi-

fication of infectious diseases does not yet include the true nature of the processes. Added to this is the fact that the group of miasmatic-contagious diseases is by no means small, and before very long we shall have to decide whether to include in it diseases which, heretofore, we did not know whether to call contagious or miasmatic, as, for instance, cerebro-spinal meningitis, erysipelas, mumps, acute articular rheumatism, lobar pneumonia, etc.

The names of the various diseases I have mentioned, gentlemen, will at once suggest to you the great variety of infectious processes which exist. The consideration of each would fall, however, under the domain of special pathology. All that interests us at this point is the fact that, in so many of them, inflammation plays such an important part. Erysipelas and epidemic meningitis are such typical inflammatory processes, that it is impossible, on anatomical grounds alone, to distinguish them from non-infectious inflammations of the skin and pia mater; and even where the chief symptoms of an infectious disease are not of an inflammatory nature, it is, nevertheless, nothing uncommon for intercurrent inflammations to occur; thus, the abscesses in pyæmia, and the numerous inflammations, both acute and chronic, in syphilis. You see, therefore, that in speaking of the process of inflammation as a whole, we are abundantly justified in seeking for the cause of infectious inflammations, or, from our standpoint, for *the reason why, in infectious diseases, the walls of the blood-vessels are affected.*

If we ask ourselves, then, what the nature of the poison is, I think we may from the first safely say that it does not exist in the vital fluids in a state of solution; for how can we conceive of a poisonous solution attacking the vessels of a certain part of the body only, and those frequently not the ones through which the poison was either originally introduced or finally eliminated? A second weighty factor in this consideration is the one that the different viruses of infectious inflammations, as of infectious diseases altogether, are capable of reproducing themselves to unnumbered multitudes.

As you all know, the contagious matter from the vesicle of cow-pox can be so indefinitely increased, by successive inoculations, that thousands of persons may be vaccinated from what was originally contained in one drop of the fluid. The same holds true of the contagium of measles, of scarlet-fever, of gonorrhœa, of syphilis, and other infectious diseases. What substance, I ask you, gentlemen, is there which, dissolved, should have such a power unknown to any chemical body? Many chemical bodies, it is true, have the property of becoming infinitely divided, as odoriferous substances, for instance, but in such cases the effects become less and less as the division increases. If it, therefore, be no solution, it must be a corpuscular poison which enters the body and increases in it. Already, in 1846, the idea of a *contagium vivum* was broached by Henle; but it met with no general acceptance, because, with the means then at command, the existence of such a body could not be ocularly demonstrated. There is nothing, perhaps, which better justifies the assumption of such a view than the history of trichinosis. In trichinosis we have a disease running a specific and typical course, and which was formerly thought to be and classified as a miasmatic fever. Now we know that trichinæ—highly organized living beings, which are transferred from one animal to another and from them to man—are the cause of the severe inflammations which occur in the muscles of infected individuals. In this case we know exactly the mode of the development of the infecting organism; we know how it is spread from the rat to the pig, and from the latter to man, and in what way the transfer takes place. Is the process any less one of infection on that account? And yet for years it was stoutly maintained that trichinosis was a *parasitic* disease, and that its origin, due to such gross organisms whose presence, if not form, can be seen with the naked eye, could not be compared to the subtle poisons which caused the ordinary infectious diseases.

But, gentlemen, I hope to be able to show you, a little later, that all infectious diseases are parasitic. If all infections depended on such easily seen organisms as the trichinæ, we would not have had to wait till to-day for the demonstration of the parasites. Numerous experiences, as I mentioned to you in the lectures on puriform thrombi and on traumatic inflammations, go to show that we have to seek for our causes among that great family of low organisms, the *Schizomycetes;* and, as a matter of fact, the investigations into the dependence of the infectious diseases on this class of microphytes have, during the last decade, been pushed in a manner which has yielded truly brilliant results.

Before going any further, allow me to draw your attention to a research, dating from this period, which has shed such a bright light on one of the most dangerous infectious diseases, that thereby the comprehension of the nature of all analogous processes has been vastly facilitated. I refer to anthrax, or splenic fever. Ever since the blood of animals affected with this disease has been found to contain hyaline, motionless, rod-shaped bodies, so-called *bacteridia*, or *bacilli*, endeavors have been made to trace a connection between them and it.

Davaine, who as early as 1850 discovered the bacilli, tried by inoculations to show that these were the contagium, and however convincing his experiments appear (and especially striking was the fact that, while the bacilliferous blood of pregnant animals was capable of inoculating, the blood of their fœtuses, containing no bacilli, was entirely harmless), still, other observers could not convince themselves that after every successful inoculation bacilli were found in the blood of the animal inoculated, and yet the blood of the latter still had the power to produce the disease. Furthermore, it was urged, and apparently on good grounds, that anthrax has an undoubted connection with certain telluric conditions, for it occurs endemically in certain localities with a moist soil. All the doubts, however, which still hung about the subject were dissolved, as if by magic, by the researches of Koch, of Breslau. He showed the natural history of the *bacillus anthracis* to be as follows: The rods—the bacilli—multiply with extraordinary rapidity in the blood, and other fluids of the living animal, by elongating and dividing transversely. In the blood of dead animals, or other suitable propagating fluids, the bacilli develop, in the presence of air and between certain limits of temperature, to long, undivided filaments, in each of which a single row of spores makes its appearance. These spores, again, under similar conditions of habitat, air, and temperature, become the original bacilli. Another and very important point which Koch showed was that the life of the bacillus itself is of short and uncertain duration, and that under no circumstances do they live more than a few weeks at the most, and also that comparatively slight changes of temperature, or drying them, or exposing them to the action of distilled water, kills them. The spores, on the contrary, have a remarkable tenacity of life. They may be heated to any temperature below that necessary to coagulate albumen; may be put into a four or five per cent. solution of carbolic acid, or into strong alcohol, or may be kept dried for years, without impairing their power of reproduction.

We may say, therefore, that fluids containing spores are always infectious; whereas fluids containing the rods are only infectious when these are in the stage of active development, consequently, anthrax may be spread in

two ways—in the first place, by a direct transfer of bacilliferous blood, or other fluid from an infected animal, to a cut or abrasion in a healthy animal or man, hence its *contagiousness*. The other way is, that from the bacilli in the blood of dead animals, buried as they usually are in shallow pits in the damp earth, spores are produced which remain capable of development for an almost indefinite period of time. When these, therefore, by being in the grass, or other objects where the cattle feed, gain entrance by slight wounds into the system, the disease is again produced, and in this case really from the soil, that is to say, by a *miasma*.

ORIGINAL ARTICLES.

THE INFLUENCE OF OPERATIONS UPON THE PROLONGATION OF LIFE AND PERMANENT RECOVERY IN CARCINOMA OF THE BREAST.[1]

BY SAMUEL W. GROSS, A.M., M.D.,
SURGEON TO, AND LECTURER ON CLINICAL SURGERY IN, THE JEFFERSON MEDICAL COLLEGE HOSPITAL, AND THE PHILADELPHIA HOSPITAL.

THE convictions are steadily gaining ground that carcinoma of the breast is curable, and that it is primarily a local affection, and not the expression of a constitutional taint, dyscrasia, or diathesis. In favor of these views—which are held by Virchow, of Berlin, Billroth, of Vienna, Fischer, of Breslau, Esmarch, of Kiel, Nussbaum, of Munich, Volkmann, of Halle, Kocher, of Berne, Erichsen, Hutchinson, Sir William Gull, Simon, Moxon, Bryant, Arnott, Payne, Green, and formerly by De Morgan and Moore, of London, and by Gross, Parker, Peters, Neftel, Richardson, Moore, and McGraw, of the United States—the course of the disease shows that visceral tumors are preceded by signs of extension of the cellular elements of the growth into the adjacent tissues and by infection of the associated lymphatic glands; and they are, moreover, sustained by the results of surgical interference, the latter of which furnish the motive for this paper.

In view of the inevitably fatal progress of carcinoma of the breast when uninfluenced by operation, the great questions to be considered from the standpoint of pathological histology are, whether the knife prevents, first, local dissemination; secondly, lymphatic involvement; and, thirdly, the development of metastatic tumors?

1. The answer to the question—does surgical intervention prevent the invasion of the skin, connective tissue, muscles, and walls of the chest?—should be affirmative in a certain proportion of instances. Observation during life and during operations indicates that the adjacent tissues are infected in 90.82 per cent. of all instances; while of 395 cases in which this point could be traced, there was local recurrence, after removal, in 315, or 79.74 per cent. Hence extirpation precluded continuous invasion of the surrounding tissues in 10.08 per cent. of all cases, a proportion which approximates that of the permanent recoveries, as we shall see presently.

2. In regard to the second question—does extirpation prevent infection of the associated lymphatic glands?—the reply must be that it certainly does. Thus, of 657 cases, glandular implication was witnessed in 422, or 64.23 per cent., when the patient first came under observation. In all the axillary glands were enlarged, and along with these the supraclavicular glands were involved in 27, the infraclavicular in 5, and the cervical in 3. Of 114 operations in which this point is noted, the recurrent disease was seated in the glands in 46, or 39.31 per cent., or in 24.92 per cent. less than when the affection was not influenced by interference; and the fact is noteworthy that the glandular recurrence was more frequent by 19.64 per cent. when the breast alone was removed than when it was extirpated with the glands.

3. In replying to the third question, it should be remembered that metastatic tumors are not always developed. Thus, of 740 patients dead of carcinoma, in whom the disease pursued a natural course, or who had submitted to operation, contamination of the viscera was discovered in 303, or in 40 per cent., so that more than one-half succumbed from the intensity of the local disease and the pernicious effects exerted upon the general nutrition through the loss of blood, offensive and exhausting discharges, and suffering. Of the entire number, in 252 the case was not influenced by operation, and metastatic growths were found in 157, or 62.30 per cent., while of the 488 subjected to the knife, the disease had extended to the viscera in only 146, or 30 per cent. As the course of the disease when left to itself shows that metastases are absent in 37.70 cases out of every hundred, and as they are wanting in 70 out of every hundred of the patients dead after operation, it follows that operations prevent implication of the inner organs in 32.30 cases out of every hundred.

Having thus seen that local extension, reproduction in the glands, and the formation of metastatic tumors may be obviated by the removal of the breast, we are justified in inferring, first, that life may be prolonged, and, secondly, that a permanent recovery may be effected by surgical intervention.

1. In regard to the first deduction—namely, the extension of life—an analysis of 67 cases which pursued a natural course, indicates that the average life was 27 months. Of 224 patients, on the other hand, who died after interference with local or general reproduction, the average duration of life was 39 months; so that extirpation adds one year of life.

2. The question of permanent recovery after operation must be based upon the study of the typical course of the affection, which demonstrates that certain events which happen at certain times should determine the date at which a cure may be regarded as being assured. Volkmann[1] states that "if a year has elapsed after operation, and the most careful examination fails to detect evidences of local recurrence, enlargement of the glands, or visceral implication, we may begin to hope that a permanent result will be attained; and that a cure is generally assured if two years have elapsed, while it is rendered almost certain after the expiration of three

[1] Read before the New York Academy of Medicine, January 19, 1882.

[1] Beiträge zur Chirurgie, 1875, p. 325.

years." As I have pointed out elsewhere,[1] the average date of death from metastases is 31.2 months; and that local reproduction is witnessed in only one case out of every two hundred, after the expiration of three years. Hence, I assume, with Volkmann, that the result may be said to be final if the patient survives over three years without local or general recurrence after the last operation, or has died of some intercurrent malady under the same conditions. Of 524 cases of scirrhous, medullary, colloid, and atrophying carcinoma, in which the result is known, 57, or 10.87 per cent., or 1 in every 9.19, fulfilled these requirements, 53 being still alive at the date of the last reports. The average duration of life after operation was six years and five months, and the disease had existed, on an average, for seventeen months and a half before surgical intervention, so that the average duration of life was seven years and ten months. Of the cases which ran a natural course, only 1.5 per cent. survived six years; while of the cures, 31.57 per cent., or nearly one-third, were free from disease after the expiration of six years. In speaking of the duration of life after operation, Sir James Paget[2] says: "I am not aware of a single clear instance of recovery: of such recovery, that is, as that the patient should live for more than ten years free from the disease, or with the disease stationary." Applying this severe test, I find that 10, or 1 in 5.7, fulfilled this requirement, 4 being free from recurrence for between ten years and one month and ten years and ten months, 2 for between eleven years and two months and eleven years and nine months, 1 for twelve years, 1 for thirteen years and eight months, 1 for fourteen years and seven months, and 1 for fifteen years and seven months.

In connection with the 57 cures, there are several interesting points which are of the first importance in influencing the prognosis after operation. In 9 instances there was repullulation. In 6 there was one recurrence; in 2 there were two reproductions, respectively, in twelve months and four years; and in 1 there were three recurrences in four years. In these three cases the subjects were free from disease for three and a half, four and a half, and twelve years after the last operation; so that, as in sarcoma of the breast, recurrent tumors should be freely extirpated as soon as they appear.

Another practical point is that glandular implication is not a bar to operation. In 18, or nearly one-third, of the 57 permanent recoveries, infected axillary glands were removed, and in several of these cases there were nodules in the skin, and the upper layer of the great pectoral muscle was excised. Even if the glands be permitted to remain, it does not follow that the progress of the disease may not be arrested, as their enlargement may be due to irritative hyperplasia and not to carcinomatous degeneration. In 3 cases in which they were not interfered with the patients were free from recurrence, respectively, for five years and nine months, six years and one month, and ten years and ten months. Other interesting points in regard to the prognosis after operation are that recurrence is more frequent in the axilla, by 11 per cent., when the breast alone is amputated, than when the glands are simultaneously removed, and that reproduction takes place four months earlier after the former than after the latter procedure.

In this connection I may call attention to the fact that absence of glandular implication does not afford an absolute guarantee that secondary deposits are not already present in the viscera, since in one example out of every eight metastatic tumors are formed without the intervention of infected glands.

In the final cures the operation was practised when the affection had already existed, on an average, for seventeen months and a half, or when the skin, the connective tissue, and the lymphatic glands are usually implicated. Hence, it was not performed early, or at a period which is best fitted for insuring immunity from reproduction; nor was it by any means always complete. Thus, of 53 cases in which the extent of the operation is noted, the breast was amputated in 25, the breast was amputated and the axilla was cleaned out in 16, the tumor alone was extirpated in 10, and extirpation, with the removal of infected glands, was practised in 2. The disease had been observed for twenty-six months, and the recovery averaged six years one month and fourteen days, for the amputations of the mamma; it had existed for seventeen months, and the cure had lasted for five years and eight months, for the amputations of the mamma and removal of the glands; and its duration before operation was nine months and thirteen days, and the average life afterwards was five years, eight months, and seven days for the partial operations. Of the 53 cures, the 16 in which both the breast and the glands were removed are alone to be regarded as having been subjected to radical operations, since every possible source of local and general recurrence should be gotten rid of to constitute a thorough operation; and I now make it a rule to amputate the mamma with its investing fat and skin, search for any outlying lobules, dissect the fascia off the pectoral muscle, and open the axilla with a view to its thorough exploration, and the removal of any glands that may have escaped observation previous to interference. If the muscles are infiltrated, they should be cut away with a bold hand, and the wound, especially in the vicinity of vessels, along the lymph sheaths of which extension of the disease not infrequently takes place, should be seared with the hot iron.

If such unexpected results, namely, one cure out of every nine operations and one-fifth, are attainable by procedures of which seven-tenths must be regarded as inadequate to remove all affected tissues, what degree of success may we not reasonably expect from early and radical measures? As soon as women have learned that a permanent recovery may be anticipated when the disease is in its incipiency, they will apply sooner to the surgeon for relief, and there is every reason to believe that the ratio of cures will be greatly increased.

The results that I have indicated—and they are derived from the recent and trustworthy statistics

[1] A Practical Treatise on Tumors of the Mammary Gland, p. 164.

[2] Lectures on Surgical Pathology, 3d ed., p. 649.

published by Winiwarter,[1] Oldekop,[2] Henry,[3] and Estlander,[4] have not been attained without a very considerable mortality, since of the 602 operations, 104, or 17.27 per cent., were fatal from the immediate effects of interference. The rate of death is about 10 per cent. for partial operations; 7.69 per cent. for amputation of the breast, and 23.10 per cent. for amputation of the mamma and extirpation of the glands. Hence partial extirpations should be discarded, as they are more fatal, possibly from aiming at primary union, than removal of the entire breast, and as they hold forth little prospect for permanent recovery. The reason for the excessive mortality when the mamma and axillary glands are removed is to be found in the defective manner in which the axillary wound was managed in a large proportion of the cases. Thus of 187 operations of this description—and they constitute 68 per cent. of the entire number—Billroth[5] lost not less than 40, or 65 per cent. of the entire number of deaths, of which 25 were due to pyæmia and septicæmia, which were frequently combined with hæmorrhage from the axillary vessels, 3 were due to hæmorrhage alone, 11 to erysipelas, and 1 to pneumothorax from opening the pleural cavity. Instead of trusting to ligation of the divided veins, against which his early teachings had prejudiced him, he resorted to plugging the wound; but he states that since he has found that veins may be tied with impunity his results are improving. In the future I believe that the mortality from radical procedures will not reach 10 per cent., since of 17 cases—15 of which occurred in hospital practice—in which I amputated the entire breast and its coverings, removed the pectoral fascia, and opened the axilla, I have lost only one, the subject having been a fat woman, who was impressed with the idea that she would not recover. In 14 of these cases infected glands were extirpated, and in 3 large portions of the pectoral muscles were cut away.

From all the data contained in the paper, I believe that I am warranted in framing the following practical conclusions:

1. That surgical intervention in carcinoma of the breast tends to retard the progress of the disease by preventing local dissemination, implication of the associated lympathic glands, and the development of visceral tumors.

2. That local reproductions do not militate against a permanent recovery, provided they are freely excised as soon as they appear; and that lympathic involvement does not forbid operation, since infected glands were removed in more than one-third of the examples of final cure.

3. That the subjects are almost without exception safe from local and general reproduction if three years have elapsed since the last operation.

4. That the risk from operations is outweighed by the benefits which accrue from them, since they not only add twelve months to life, but also cure more than one-half as many patients as they destroy.

5. That all carcinomata of the breast, if there are no evidences of metastatic tumors, and if thorough removal is practicable, should be dealt with as early as possible by amputating the entire mamma and its integuments, dissecting off the subjacent fascia, and opening the axilla with a view to its exploration and the removal of any glands which were not palpable prior to interference.

ON THE

TREATMENT OF POSTERIOR HYPERTROPHY OF THE INFERIOR TURBINATED BONES.[1]

BY FREDERICK I. KNIGHT, M.D.,
INSTRUCTOR IN LARYNGOSCOPY IN HARVARD UNIVERSITY.

WITHIN the memory of even the younger members of this Society, nasal catarrh was one of the "opprobria medicinæ." The physician felt annoyed at being asked to prescribe for it, and perhaps almost vexed with his patient for having such a thing. The patient deriving no relief from sniffing up salt water or chlorate of potash solution, soon took to empirical remedies, and the worst sufferers have usually faithfully tried all the vaunted specifics in turn.

Little real advance was made in the knowledge and treatment of this affection until the discovery of the use of the laryngoscope led to the illumination of the post-nasal region, and to the study and treatment of the upper air passages as a specialty. This special study has led to the knowledge that, as in the urethra, so in the nose, a catarrh is often kept up by a stenosis. Among the most common causes of obstruction of the nares, is hypertrophy of the turbinated bones, especially the inferior. This is, strictly speaking, an hypertrophy of the mucous and sub-mucous tissues, and not of the bone itself. Another common cause of obstruction, and of the continuance of a post-nasal catarrh, is hypertrophy of the adenoid tissue at the vault of the pharynx. Both of these forms of hypertrophy also very seriously affect the quality of the voice.

The removal of these hypertrophies constitutes one of the greatest advances yet made in the treatment of the affections of this region. Of the treatment of adenoid hypertrophy at the vault, I shall not now speak.

The hypertrophy of the mucous membrane of the turbinated bones may involve the whole bone, or may occur almost or quite exclusively on the anterior or posterior portion.

The anterior form is more accessible and earlier received successful treatment. In regard to it, I will merely say that if the hypertrophy is considerable, in whatever way done, whether by cutting or tearing or cauterization, the treatment of the redundant tissue must be *destructive*. Pressure and other means of producing absorption may give temporary relief, but in no way approximate a cure.

The special topic which I wish to introduce tonight is "Posterior Hypertrophy of the Inferior

[1] Abstract of a paper read before the Boston Society for Medical Observation.

Turbinated Bones," which requires different treatment from the anterior form. The hypertrophy here occurs in the mucous membrane, and in the erectile tissue of Bigelow, which is situated between the mucous membrane and the bone.

The symptoms produced by this condition are:

1. Obstruction to nasal respiration.

This may be so complete as to necessitate breathing through the mouth, with its well-known discomforts and evils.

2. Difficulty of removing catarrhal secretion, either by blowing the nose or by means of the douche or syringe.

3. Serious modification of the voice, production of the obstructed quality usually improperly called nasal.

4. Deafness produced either by direct pressure upon the orifice of the Eustachian tube, or by keeping up the catarrhal condition in the neighborhood.

5. Impairment of the sense of smell, although the olfactory nerve is not distributed to this bone, by stopping the draught through the nose, which seems to be necessary for the enjoyment of this sense, and indirectly by keeping up a catarrhal condition of the other bones and septum narium.

The only treatment which has proved at all efficacious for the removal of this condition, has been such as would actually remove a considerable portion of the hypertrophied tissue. Touching the posterior ends of the bones with nitrate of silver, fused on ingeniously devised instruments, with the aid of the rhinoscopic mirror, was a delicate operation, but did little permanent good. It gave, perhaps, a little temporary relief by a superficial action on the mucous membrane. Tearing away the mucous and sub-mucous tissues by means of strong forceps was a more efficient, but a very painful and barbarous, operation. The use of strong acids and the galvano-cautery are dangerous, on account of the proximity of the Eustachian tube and middle ear, and serious results have been reported from the use of the latter in this region.

The best instrument yet devised for the removal of this posterior hypertrophy of the turbi-

nated bones, is the wire snare of Dr. Jarvis, of New York, and made by Caswell, Hazard & Co. This instrument consists of two metal canulæ, the shorter sliding freely upon that part of the longer next the operator. The surface of the main canula occupied by the secondary one, is threaded for the movement on its surface of a milled-nut. No. 5 piano wire, which is very strong and capable of cutting through the hardest tissues, is passed through the main canula and attached to two pins on the proximal end of the smaller one. A slight indentation upon the small canula fits a corresponding surface on the large one. This arrangement prevents rotation of the secondary canula, and so overcomes the tendency of the wire to twist and become loosened from its attachment to the growth. The nut, when turned, pushes the outer canula before it, and thus draws home the wire noose in the inner.

Dr. Jarvis gives the following directions for its use: If there is difficulty in getting a good view of the parts on account of the tendency of the patient to gag, the soft palate may be tied up by means of a tape passed through the nares. Giving the wire loop a twist towards the side of the nose occupied by the growth, it is fixed by a turn of the nut, and passed into the nostril. The rhinoscopic mirror being held in one hand, the position of the wire loop in the posterior nares is carefully watched while it is steadily advanced with the other hand, until it is seen to encircle the growth. The tip of the wire loop has already by excavation been made to assume a point considerably to one side of the axis of the main canula; hence firm pressure is exercised upon the anterior part of the base of the growth by the end of the canula, and at the same time the apex of the wire loop is pressing firmly on its posterior border. On drawing the wire home, the tissue is cleanly divided, and, if not too large to pass through the nares, it will generally be drawn out clinging to the snare. Traction should be made very slowly, stopping at short intervals, in order that the hæmorrhage may be as little as possible.

Several questions will present themselves to one about to use this instrument for the first time:

1. Is there any danger, after having engaged a mass of tissue in the loop, of being unable to complete the operation, in other words, of getting stuck? It at once occurs to the mind that you can't go backward; can you always go forward? It seems as if there ought to be no difficulty of this kind; the wire is very strong, and in one case Dr. Bosworth cut through a hard fibrous tumor with it. Yet some gentlemen have found this difficulty, and their cases should be reported, in order that the least trouble may be recognized and guarded against. It would be a very awkward thing for the wire to break in the canula, or anywhere except at the apex of the loop; but if fresh wire is used, this is not likely to happen, for the wire is very tough.

2. How much pain is caused by the operation? Dr. Jarvis sets it down as very little. In my experience, after the introduction of the instrument, which is naturally somewhat painful, there is pain only when the screw is turned, then it is considerable. It is no more, however, than a patient who has suffered obstruction, will willingly stand to get rid of it.

3. How much hæmorrhage follows the operation? If only a few turns of the nut are made at once; so that an hour or two are consumed in the operation, the hæmorrhage is usually slight; if, however, the

operation is hurried, it may be profuse. If the palate is tied up previous to the operation, the tape could be used for drawing a plug into the posterior nares, if this should be deemed necessary. To illustrate this method of treatment, I will make a brief report of a case:

Miss A., a singer and teacher of singing, had suffered from post-nasal catarrh and obstruction for three years, the symptoms being much worse when the wind was east, and least troublesome in a south wind. The presence of flowers, especially of roses, excited violent fits of sneezing. The sense of smell was lost.

I have seen Miss A. at various times during the past three years, and prescribed various remedies for the relief of her symptoms. Last summer she appeared suffering from so much nasal obstruction as to very seriously affect the quality of the voice. On examination of the posterior nares I found them completely blocked by swelling of the turbinated bones, especially the inferior. There was also swelling of the mucous membrane of the septum.

It seemed imperative to undertake some radical treatment. I accordingly extirpated the posterior part of both turbinated bones, at different sittings, by means of the Jarvis snare.

With the first operation there was considerable hæmorrhage, the wire having been drawn home too rapidly, only twenty minutes having been consumed. At the second operation considerably more time was allowed, and the bleeding was much less. The relief to the breathing was immediate.

Recently the patient has experienced some obstruction from swelling of the posterior ends of the *middle* turbinates, which will probably require the same treatment.

A CASE OF POISONING BY SULPHATE OF MORPHIA TREATED BY ATROPIA.

BY C. F. KING, M.D.,
OF MANDAN, DAKOTA TERRITORY.

FRANKIE M., one of the "demi-monde," took fifteen grains of the sulphate of morphia with suicidal intent. I saw her about one hour after; symptoms as follows: Pulse very feeble and rapid, respirations labored and stertorous, pupils contracted. I at once gave her ten grains of sulphate of zinc, which produced free emesis. I then gave a large quantity of warm water and commenced walking her, and in about forty minutes gave her another dose of zinc, by which means I thoroughly washed out the stomach. About this time the lips became cyanotic, and there was complete insensibility, and the surface of the body was cold. I then gave, hypodermically, one-tenth of a grain of sulphate of atropia, and in about thirty minutes one-fifth of a grain more. The cyanosis soon disappeared, the pupils enlarged, the body became warm, and the respirations quite easy and natural, and I left her, about four hours afterward, resting quite comfortably. She made a good recovery, and thirty-six hours later was walking the street.

The treatment in this case was certainly heroic, but the condition of the patient seemed to demand it, and the result justified it. I have no knowledge of any case in which such large doses of atropia were administered.

HOSPITAL NOTES.

THE WESTERN PENNSYLVANIA HOSPITAL.

Service of W. F. DALY, M.D.

A CASE OF AGGRESSIVE MANIA, CONNECTED WITH PERSISTENT HIGH TEMPERATURE, IN TYPHOID FEVER, SUCCESSFULLY TREATED WITH THE COLD BATH.

KATE L., a stout, dark-complexioned Irish girl, an employé in the hospital laundry, engaged chiefly in washing the linen of typhoid patients, was brought into one of the wards with typhoid fever. In due time the "rose spots" made their appearance on the abdomen, sordes upon the teeth, dull, dusky countenance, diarrhœa (involuntary), and mental stupor. Temperature, 105; pulse, 130; respiration normal. No chest complications. Abdominal iliac tenderness, gurgling.

Treatment by four-drop doses tinct. aconite root and ten drops of iodine solution every three hours (10 grs. ad ℥i glycerin), with cold sponging. Under this treatment the pulse varied but little, and the temperature fell to about 104⅘ in evening, and was little below that in the morning, as shown by the temperature cards, and the mental stupor was superseded after five days by a maniacal condition of the most aggressive character and utter insomnia, notwithstanding the careful administration of thirty-grain doses of the bromide of potassium for the first day or two, until refused by the patient, who did not sleep for seven days and nights, the maniacal excitement consisting of biting the nurses who attempted to restrain her, wrenching the arm of one of the nurses, causing subluxation, throwing tumbler or pitcher at the attendants, absolutely refusing food and drink. The utter impossibility of nourishing, restraining, or keeping this patient clean, what with the involuntary alvine and urinary discharges and her constant maniacal condition, a straight-jacket was put on, and afterwards a broad soft belt around her trunk, with wristlets, and all fastened to the bed. Nourishment per enemata was not retained, nor were medicines, and the temperature keeping up with the pulse, she was fast exhausting herself. The prognosis concurred in by the house staff and Dr. Daly was that death must supervene before many days.

Hers was a case essentially proper to be treated by the cold bath, which was suggested and called into effect. The patient was placed in the bath at 98°, and during ten to fifteen minutes it was lowered to 50° or 40°, without at first having any perceptible effect upon the temperature more than a reduction of one and a fraction of a degree for the first week, but the patient slept a short time after each bath, given every three to six hours, according to exigencies. After six or seven days' persistent effort of this kind, the rectum was more retentive of nourishment. No medicines whatever were given, even by the bowel, after the baths were begun, and for two weeks no food was taken by the mouth. The aggressive mania returned regularly after the soothing effect of the bath wore off, and the rest and quiet as invariably followed the cold bathing.

The girl is now well, after about two months' illness, and able to leave the hospital.

Remarks.—This case occurring in a strong, young girl of nervo-sanguine temperament, and with all the typical conditions of typhoid fever, contracted doubtlessly from constant employment in washing the linen and clothing of other typhoid patients, was thoroughly saturated with the most virulent form of the "causis morbi," hence, with this persistent high temperature, the superheated blood being pumped rapidly through the brain, was probably all-sufficient to cause the maniacal demonstration of so persistent a character.

In the service among the typhoid fever cases serious

lung complications are the only conditions contraindicating the use of the cold bath in high temperature.

WORKHOUSE AND ALMSHOUSE HOSPITALS, NEW YORK.

CASE OF DERMOID CYST OF AN UNDESCENDED OVARY.

(Under the care of R. VAN SANTVOORD, M D., Visiting Physician to the Hospitals.)

THE following case is of sufficient rarity to be worthy of record:

In August, 1881, my attention was called to a woman, aged fifty (?) years, who had been admitted to the hospital on the previous day, suffering from some acute febrile disease. During the examination a tumor was felt in the abdomen, about two inches to the right and above the umbilicus. It seemed to be about as large as a fist, but could not be satisfactorily defined, owing to coexisting tympanitis. On palpation, a distinct and peculiar crepitation could be felt. Nothing was known of the history of the patient previous to the present illness.

The patient was rapidly sinking at the time of the examination, and died about twenty-four hours after it. On autopsy, the cause of death was found to be acute lobar pneumonia, involving the upper part of the left lower lobe. On opening the abdomen, a tumor with a smooth surface was seen projecting above the intestines in the position above indicated. The distended colon partly covered it in on the right side and above. The small intestines were crowded to the left and downward. On drawing back the intestines an oval tumor, about 6½ inches long and 3½ to 4 inches in diameter, was seen lying between the spinal column and the right kidney. The right Fallopian tube passed vertically upward from the uterus to the lower end of the tumor, with which what was evidently its fimbriated extremity became fused. There was no normal ovary on the right side. The os uteri showed the usual slight bilateral laceration indicative of former pregnancy. The uterus, left ovary, and Fallopian tube presented nothing abnormal. The tumor was behind the peritoneum. There were no adhesions to it of the surrounding viscera. It was attached over a considerable area of its posterior surface to the posterior wall of the abdomen by loose areola tissue. On section the walls of the tumor were found to be extensively calcified. A quantity of yellow, fatty fluid escaped, which quickly solidified to the consistency of butter. Several masses of long, light-colored, fine hair, matted together, were found. There were also fatty masses, probably made up of hair, epithelium, and fatty matter, more or less closely adherent to the inner surface of the cyst. This inner surface was covered with fully-developed cuticles. No other abnormalities were observed in the abdomen.

The location and anatomical relations of the tumor make it evident that it was to be regarded as a *dermoid cyst of an undescended ovary*.

Remarks.—According to Peaslee, three-fifths of all dermoid cysts are ovarian (129 out of 188 cases). He does not mention that any of these occurred in an *undescended* ovary. He refers to T. Safford Lee and J. F. Meckel (Peaslee on *Ovarian Tumors*, first edition, p. 84) as recording cases of dermoid cysts found "behind the peritoneum upon the posterior muscular walls of the abdomen." It seems possible that these cases might have belonged to this category. Schroeder (*Ziemssen's Clyclopædia*), Wells, Thomas, and Emmet make no allusion to the occurrence. Atlee (*Ovarian Tumors*, p. 188) records a post-mortem examination of a case of dermoid cyst, ten inches in diameter, "occupying mainly the umbilical region," and imbedded in folds of large intestine. All the surrounding viscera were closely adherent to it. No connection with the uterus could be traced, but from the absence of the left ovary in its normal position, it seems fair to presume that it was ovarian, and that its uterine connections had been overlooked, owing to the visceral adhesions. Atlee regarded the case as unique.

MEDICAL PROGRESS.

A RARE FORM OF PREGNANCY.—In a recent number of the *Archiv für Gynäkologie* a case is recorded which, on account of its exceeding rarity, deserves notice. It occurred in the clinique of Prof. LITZMANN, of Kiel, and is reported by Dr. WERTH. It was one of pregnancy in the imperfectly developed horn of a bicorned uterus, the fœtus, fully developed, being retained beyond the full term. The patient was thirty-nine years old, and had had two children. She last menstruated in December, 1878. Fœtal movements were felt about the end of May, 1879. In the latter end of October the fœtal movements were unusually vigorous, and then ceased. Then came pain; and at the end of November, feverishness, sanious vaginal discharge, and wasting. She was taken into the hospital, and as, on examination, the os uteri was found large enough to admit the finger, and the fœtal head could be felt within it, the diagnosis was made that it was a case of retention of a dead child in the uterus. On February 14, laparotomy was performed: a decomposing, but fully developed, child was removed, and then the sac, at first supposed to be the uterus, which had contained the fœtus, was extirpated. On examination this sac was found to have only one set of uterine appendages. The patient died on the 16th from peritonitis. It was then found that the uterus was bicorned, the fœtus having developed in the right horn. The right kidney was absent. A corpus luteum was present in the right ovary. The author has only been able to find one case on record which at all resembles this, viz., one published by Turner.[1] We may add that Dr. Barnes (in his work on Diseases of Women) has hazarded the speculation that many cases reported as extra-uterine gestation, in which fœtal bones, etc., were discharged per vaginam, were really cases like this one.—*Med. Times and Gazette*, Dec. 3, 1881.

CONTUSION OF THE TESTICLE.—From an elaborate article on this subject by Profs. MONOD and TERRILLON, the following conclusions are drawn:

1. Contusion of the testicle is frequently followed by transient pains, without any appreciable local lesion, and without subsequent inflammatory reaction.

2. When the contusion is more severe, incontestable material lesions are produced in the parenchyma of the testicle, which may give rise to a more or less severe inflammatory reaction, leading, generally, to atrophy of the organ, or, more rarely, to suppuration.

3. It may then be said that traumatic orchitis is most frequently an atrophic orchitis, with a consequent grave prognosis as to function. Three degrees may be recognized: The first is characterized by simple hæmorrhages into the cellular tissue; the second by hæmorrhages corresponding to rupture of the semeniferous tubules; and the third by rupture of the albuginea, with escape of the tubules into the vaginalis; this form is accompanied by crushing of the testicle.

4. Atrophy is particularly frequent in youth; suppuration in the aged and debilitated.

5. The epididymis may be affected at the same time as the testicle, but it shows less tendency to atrophy.

[1] On Malformation of the Organs of Generation. Edinburgh, 1866.

6. The peripheral lesions, whether located in the vaginalis or in the periepididymal cellular tissue, often mask the original injury, and are frequently a cause of error.

7. The frequency with which orchitis follows contusion has been greatly exaggerated. It is frequently confounded with urethral orchitis; careful examination of the urethra will enable this error to be avoided.

8. Certain forms of orchitis, depending upon diathesis, are often wrongly attributed to a traumatism; the injury can, however, in such cases, prove the determining cause, as, for example, a contusion can render evident a tubercular or syphilitic affection of the testicle in persons affected with these diatheses, or can hasten the development of tubercle which had been previously latent.—*Arch. Gén. de Méd.*, Dec., 1881.

TREATMENT OF TONSILLITIS AND HYPERTROPHY OF THE TONSILS BY BICARBONATE OF SODA.—Dr. ARMANGUÉ reports in *Revue de Thérapeutique* seven cases of tonsillitis cured in less than twenty-four hours by the bicarbonate of soda. This method of treatment was introduced by Dr. Giné, Professor of Clinical Surgery, who employed bicarbonate of soda locally either by insufflation, or directly applied by the finger of the patient. The applications should be frequently repeated until the disease disappears. Dr. Giné relates dozens of cases in which a cure was accomplished in less than twenty-four hours, and has never seen this method fail to produce a good effect. The alleviation is almost always immediate, and is never long delayed. Its efficacy is especially marked in the prodromic period of tonsillitis, when it will invariably abort the disease. According to Dr. Giné, bicarbonate of soda does not diminish the predisposition to anginas, but only arrests their development. Excision of the tonsils is a useless operation in cases of hypertrophy of the tonsils, since the hypertrophy can be rapidly removed by frequent applications of the salt of soda.—*L' Union Méd. du Canada*, Dec., 1881.

HYSTERIA IN CHILDHOOD.—SCHMITT (*Ann. Univ. di Med. et Chir.*) confirms the existence of hysteria in children, as is admitted by numerous authors, and reports several cases seen in the clinic at Strasbourg:

1. A case of hysterical aphonia in a little girl aged seven years, and cured by the simple introduction of the laryngoscope.

2. A case of a little girl thirteen years of age, who had not yet menstruated, and who had for nine months been unable to swallow; she was cured by a single catheterization.

3. A case of an anæmic and badly-nourished little girl aged nine years, with convulsive and maniacal hysteria, which resisted all treatment.

4. A case of a little girl nine yeas old, who had a hysterical contracture, and was cured by moral treatment.

As causes of this rare disease, the author indicates anæmia, chlorosis, and inherited nervous temperament. The general condition of the patient must be improved before any treatment is attempted.—*L' Union Méd.*, Nov. 27, 1881.

MULTILOCULAR CYST OF THE KIDNEY—EXTIRPATION—DEATH.—In the *San Francisco Western Lancet*, November, 1881, there is a report of a case in which Dr. O. O. BURGESS found, on examination, a large indistinctly fluctuating tumor just below the margin of the liver. There were no symptoms of renal or hepatic trouble, nor had any been present previously. As the tumor gradually increased in size, and the patient became exhausted by the increasing pain, the cyst was aspirated, and about a pint of liquid removed. The next day the tumor was as large as ever, and was again tapped, with the same result. There being considerable difference of opinion as to the diagnosis, and the patient rapidly failing, it was determined to make an exploratory incision. This revealed the true nature of the growth, which was removed with some little difficulty. Death resulted from shock thirty hours after the operation.

From a letter from Dr. Burgess to the Editor of the MEDICAL NEWS, we definitely learn that "no apparent trace of the right kidney, in which the multilocular cyst had been developed, could be detected, either during the operation or after death. The organ, as such, was lost in the development of the cystic disease. The fact that several small renal concretions were found in the cysts was accidentally omitted from the published report. This fact seems to me of some importance in its possible relation to the causation of the disease."

FIDDLE-STRING AS A BOUGIE.—Dr. F. E. DANIEL, of Jackson, Miss., failing in a case of very tight stricture to get in the smallest ordinary bougie, used in the emergency a small *fiddle-string*. This passed in readily. Being withdrawn in a few minutes, it was found to have swollen to nearly twice its previous size. A larger one was then passed and allowed to remain fifteen minutes; this being then withdrawn, the urethra was sufficiently dilated to get in a No. 4, then a No. 6 bougie, and finally a flexible Nélaton's catheter, threaded on a fiddle-string. A second case was equally satisfactory. Dr. D. claims for the fiddle-string (catgut) cheapness, simplicity, availability, harmlessness, strength, and rapid expansion.—*Maryland Medical Journal*, Dec. 1, 1881.

SECONDARY ANEURISM OF THE RADIAL ARTERY.—In the St. Louis *Courier of Medicine* for Dec., 1881, Dr. T. J. TURPIN reports the case of a negro, aged forty-five, who had applied, in March, 1873, for treatment of an aneurism of the radial artery. The aneurism was situated about one inch above the wrist-joint, and was about the size of a partridge egg. All the diagnostic points of aneurism were unmistakably present. The patient was a carpenter by trade, and a man of very intemperate habits. Nothing was done at the time beyond directing the man to give up his work for the time being and endeavor to reform his intemperate habits. It so happened that the patient was not seen again for several months, and then the aneurism had undergone a spontaneous cure, which was complete, no traces of the aneurismal sac remaining. Early in the spring of the present year (1881) the aneurism recurred at the identical spot on the same artery, attaining a larger size than the previous one. Digital compression, not complete, but so as to mitigate the volume and force of the blood, was employed, when the aneurism rapidly disappeared, and in a few weeks no trace of it remained. The patient works steadily at his trade, and has discontinued his drunken habits for over three years.

The points of interest in this case are:

1. The extreme rarity of the morbid condition, being the third "unequivocal" case upon record.

2. The length of time which elapsed before the recurrence of the disease, viz.: eight years.

3. The facility with which a cure was effected, notwithstanding the long-continued use of alcoholic stimulants militated against the probability of such a result.

BILIARY FISTULÆ.—A curious example of multiple biliary fistulæ has been communicated by KOSACH to the Medical Society of Cologne. The cystic duct was completely obliterated. The gall-bladder, in conse-

quence apparently of the irritation of biliary calculi, had contracted adhesions to the duodenum, with which it communicated by a large fistulous opening. Near this was another opening by which the gall-bladder communicated with the colon. A third fistula existed between the duodenum and the colon. The common bile-duct was distended, and its cavity obliterated, by two biliary concretions. These lesions were not suspected during life. The woman presented no jaundice, in spite of the closure of the ducts, on account of the free passage for the bile into the intestine. She had never suffered from hepatic colic. The chief symptom was constant diarrhœa, which caused fatal exhaustion, in spite of a "canine appetite," which she strove unceasingly to satisfy.—*Lancet*, Dec. 3, 1881.

THE BLOOD IN CHLOROSIS AND PREGNANCY.—From the examination of the blood in twenty-two cases of pregnancy and in seven of chlorosis, made with Hayem's chronometer, Dr. FREDERICK WILLCOCKS draws the following conclusions:

1. That a more or less considerable diminution of hæmoglobin is found in both pregnancy and chlorosis, especially in the latter, but that beyond this fact no obvious analogy exists between them.

2. That in pregnancy the diminution of color is due to a fall in the number of red cells, and that the individual cell remains of high value. In chlorosis both the cells and the individual value are reduced, the latter being in excess of the former.

3. That the blood-state of healthy pregnancy is due to a large relative increase in the water of the plasma, and that this condition does not constitute a true anæmia, but is due to the progressive enlargement of the vascular area during pregnancy.—*Lancet*, Dec. 3, 1881.

TETANUS AFTER OVARIOTOMY.—In the *Lancet* for Dec. 3, Dr. JAS. M. BENNETT reports a case of ovariotomy, in which the operation was followed on the sixteenth day by tetanus. Atropia, quinia, physostigma, chloroform, morphia, and nicotine were used; the patient died on the eighteenth day after the operation.

GASTROSTOMY.—Recently at University College Hospital, London, Mr. MARSHALL performed the operation of gastrostomy upon a man aged sixty-five, who was the subject of malignant disease of the œsophagus, employing a method for which we are indebted to the experimental physiologists. It would be more correct to say that the first step of the operation has been accomplished, but that was by far the most serious step. The stomach was stitched to the abdominal walls by sutures which passed through the peritoneal and muscular coats of the stomach, and through the parietal peritoneum, but did not penetrate the gastric cavity. In four or five days after the date of operation, the final step, which consists in opening the stomach, will be taken; by postponing this, it is possible to maintain the wound in an aseptic condition until after the peritoneal adhesions have become firmly organized.—*British Med. Journ.*, Dec. 3, 1881.

IODOFORM POISONING.—Dr. A. HENRY, who had previously obtained very good results in carious disease by treatment with iodoform dressing, communicates to the *Deutsche Med. Woch.*, No. 34, 1881, the details of two fatal cases of poisoning from the use of iodoform in this way. No other positive cause of death could be discovered on *post-mortem* examination, and in both instances the symptoms presented were typical. The cerebral symptoms were the most prominent, consisting in extreme drowsiness, from which it was difficult to awake the patient, and which eventually ended in coma; there were also paralysis of the sphincters, aphonia, contractions of the muscles of the neck, boat-shaped retraction of the abdominal walls, and a very rapid pulse. Temperature was normal throughout. The only difference between the cases was in the acuteness with which the symptoms set in. In the first case $\frac{1}{\frac{1}{8}\frac{1}{8}}$ grm. iodoform had been used, the first signs of illness appearing on the second day, and death occurring on the sixth. In the second case $\frac{1}{\frac{1}{8}\frac{1}{8}}$ grm. iodoform were used, nine days passed, in which the patient was perfectly well; this period was followed by two days of distressing headache; then drowsiness, etc., were noticed, and the patient died on the sixteenth day after operation. *Post-mortem* examination revealed only fatty degeneration of the heart, and parenchymatous disease of the liver and kidneys, as in cases of chloroform poisoning, and in the experiments made on animals by Moleschott, Binz, etc. It remains to be mentioned only that the first patient was a drinker, well-built, and aged fifty-seven; the second was a weakly woman, aged sixty-three.—*Glasgow Med. Journ.*, Dec., 1881.

CONTAGION OF TUBERCULOSIS.—M. TOUSSAINT presented a note on this subject at the meeting of the Académie des Sciences de Paris, held on November 7, 1881. He finds that true tuberculosis, whether in the case of man, the cow, pig, or rabbit, reproduces itself indefinitely with absolutely constant and identical properties, and that it is capable of being transferred from animal to animal without losing its virulence; in fact, it becomes more virulent when often inoculated. At the start it requires four or five months to kill a pig or rabbit with tuberculosis, but with the fifth series, two months are sufficient. If thirty-five days after the inoculation one of the set of animals be killed, and from it a new animal inoculated, the latter will often die with the rest of the series.

It is especially with tuberculosis produced by culture that the greatest increase in virulence is seen. The serous fluid in a caseous gland of a cat dying from a cultivated injection, was inoculated into six rabbits; all became tubercular. Forty days afterwards one was killed; it showed already pulmonary tubercles, with which six rabbits and a pig were inoculated, the latter died in fifty-seven days, and the rabbits in sixty-eight. He has remarked that the fifth series of cultures are always more abundant and rapid than the first, and the tenth more than the fifth.—*Revue Scientifique*, Nov. 19, 1881.

DEVELOPMENT OF A SINGLE BREAST IN GIRLS.—M. DESPRÈS took occasion of the presence of a girl at his clinic to draw the attention of his class to a circumstance that causes alarm to mothers, and is sometimes judged wrongly of even by practitioners. This was an example of the development of only one breast at the age of puberty, when the belief is often entertained that this arises from the presence of a tumor. This girl was thirteen years of age, and was brought to the hospital under the idea that she had a tumor of the right breast, the left one not yet having undergone any change. Her attendant had prescribed iodide of potassium. M. Desprès at once assured the mother that it was only the natural development of the organ, and would be soon followed by the appearance of the menses and the development of the other breast. He observed to his class that while it is natural for mothers to be deceived in these cases, it should be impossible for the surgeon to be so. In fact, there exists beneath the breast a regular prominence in the form of a movable disk on the chest, without the slightest adherence to the skin, and accompanied by no pain whatever. The nipple is exactly in the centre of the tumefaction, and although the developing gland is resistant, it is never irregular, and never presents lumps. A tumor

of new formation, such as a sarcoma, is always harder, and is never found exactly in the centre of the mammary region.—*Med. Times and Gazette*, Dec. 10, 1881, from *Gaz. des Hop.*, Nov. 24, 1881.

POLYSARCIA.—A remarkable case of polysarcia was exhibited at the last meeting of the Paris Academy of Medicine by M. HILLAIRET. The subject is a female child, a little over five years of age, 1 metre 15 centimetres in height, and weighing about 136 lb. The following measurements were taken on November 27: Round the waist at the level of the umbilicus, 107 centimetres; round the chest, 102 centimetres. Circumference of the neck, 37 centimetres; of the arm at the axilla, 35 centimetres; of the elbow, 26 centimetres; of the wrist, 17 centimetres. The upper part of the thigh, the knee, and the instep measured respectively 57, 38, and 25 centimetres. The parents of the child are of average size, and their other three children are not unusually developed. Notwithstanding her enormous bulk she is able to run, and even to jump.—*Lancet*, Dec. 10, 1881.

HERPES OF THE LARYNX.—In view of the rarity of this affection, and, indeed, the doubt expressed by many authors as to its actual existence, the case reported by Dr. GOTTFRIED SCHEFF in the *Allgemeine Wiener Medizinische Zeitung*, November 22, 1881, is of interest. The patient was a man sixty years old; the affection was introduced with fever and isolated areas of redness and swelling of the mucous membrane of the larynx, with burning and stabbing pain, difficulty in swallowing, dry cough, and even, when the swelling was marked, with difficulty in breathing. After three or four days a vesicular eruption appeared entirely similar to the ordinary herpes labialis, and followed an analogous course, with the exception that no crusts were formed after the rupture of the vesicles, the excavation becoming rapidly skinned over. During the stage of inflammation Dr. Scheff used applications of ice, and later merely an expective treatment.

PENETRATING WOUND OF THE AORTA.—At the meeting of the Vienna Gesellschaft der Aerzte, on November 25, Dr. ZILLNER exhibited a specimen of a penetrating wound of the aorta, the man living for sixteen days after, and then dying from pericarditis. The course of the wound ran from underneath the right clavicle, through the pectoralis major and the second intercostal space into the aorta, in which an aperture four millimetres in length, and situated three fingers' breadth above the valves, was visible. The small size of the wound, a considerable atheromatous degeneration of the aorta, the slight retraction of its inner coat, and a possible plugging by the pericardial covering, may perhaps account for the prolongation of life in this case. Prof. Chiari observed that even a spontaneous rupture of the aorta may heal. In 1880, in the Rudolph's Hospital, while dissecting the body of a man who had died of phthisis, he met with a false aneurism of the ascending aorta, with a transverse rupture of the vessel by the side of it, which had healed. —*Wien. Med. Zeitung*, Nov. 29, 1881.

TREATMENT OF BRONCHIAL AFFECTIONS OF PULMONARY PHTHISIS BY AMMONIACAL INHALATIONS.—M. MELSENS highly recommends (*Bull. de l'Académie Belge, et Paris Méd.*, Oct. 22, 1881) the therapeutic employment of ammonia by inhalation in phthisis. Knowing that ammoniacal emanations may be respired without danger, of which the proof is the perfect health of workmen who dig guano, and also knowing the good effects of the air of cow-houses in pulmonary phthisis, effects which are generally with justice attributed to the emanations of carbonate of ammonia generated in these stables, M. Melsens conceived the idea that continuous but moderate respiration of this salt might be useful in other affections of the respiratory organs. He decided, after an attack of acute bronchitis, to make the experiment on himself. For that purpose, he wore outside his shirt a bag containing some pieces of carbonate of ammonia; after some time he was absolutely relieved from the affection; improvement set in from the first day. Several invalids who employed the same means obtained great benefit from it, even in cases of long-continued chronic bronchitis. Amongst others, a physician at Brussels, who had suffered for a long time from an obstinate cough, due to chronic bronchitis, with dilatation of the bronchi, complicated with emphysema, asthma, and sometimes with acute laryngitis. He used the bag of carbonate of ammonia, and found himself perfectly cured.—*London Med. Record*, Dec. 15, 1881.

TRANSFUSION OF BLOOD FOR HÆMORRHAGE IN TYPHOID FEVER.—At the meeting of the Clinical Society of London held on November 25, Dr. MAHOMED read notes of two cases of direct transfusion of blood for hæmorrhage in typhoid fever, in both of which, although ending fatally, there seemed to be marked temporary improvement.

THE TREATMENT OF CHOLERA.—In an article on the cholera epidemics of 1875, '76, and '77, at Damas and French India, Dr. DESPRÈS found the following formula very successful: Chloroform, 1 gramme, or 15½ grains. Alcohol, 8 grammes, or ʒij. Acetate of Ammonia, 10 grammes, or ʒiij. Syrp. of Muriate of Morphia, 40 grammes, or ʒx. Water, 110 grammes, or ʒxxviii. Mix, and take a teaspoonful every half-hour. Under the use of this prescription the mortality, which had been 80 per 100 of cases, was reduced to 28 per 100.

RAPID LITHOTRITY IN CHILDREN.—In the *Allgemeine Wiener Medizinische Zeitung* for November 29, 1881, there are reports of two cases in which litholapaxy was attempted in children, and terminated unsuccessfully. In one case, that of a boy aged six years, operated on by Prof. BILLROTH, several large fragments were left in the bladder, and false passages were made with urinary infiltration, and death as a result. The other case alluded to was operated on by Prof. Dittel, in which litholapaxy was unsuccessful, and had to be followed by lithotomy. It seems due to Prof. Bigelow to say that he has never recommended his operation as applicable to children.

PARSLEY AS AN ANTILACTIC.—Dr. STANISLAS MARTIN, after observing that the use of mineral waters interrupted the secretion of milk, states that, as an external application, parsley leaves act most efficaciously in dispersing it, and that they were used for this purpose by the Roman matrons of old. The breasts should be covered with freshly plucked leaves, and these should be renewed several times a day as fast as they begin to fade. The dispersion of the milk soon takes place.—*Med. Times and Gazette*, Dec. 10, 1881.

DUBOISIA IN THE NIGHT-SWEATING OF PHTHISIS.—Dr. FRANZEL has used pills of $\frac{1}{120}$–$\frac{1}{80}$ of a grain of duboisia in thirteen cases of phthisis and two cases of joint affection with profuse sweating, and found that it produces far less effect than atropia; it must be given for days in succession before any effect is evident, and in some instances fails completely. It also produces unpleasant effects, such as nausea, dizziness, dryness of the throat, etc. Once delirium was produced.—*Centrlb. f. d. med. Wissen.*, Dec. 10, 1881.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JANUARY 21, 1882.

THE SMALL-POX.

IN another column we print an article on the present epidemic of small-pox in the United States. The statistics given in it are sufficiently striking, although they by no means represent the full extent of the spread of the disease. This is especially the case as regards the States of Illinois and Wisconsin, where it has been slowly but steadily gathering headway during the past year, in a population having a relatively large proportion derived from the North of Europe, and to a great extent unprotected by vaccination. Vigorous efforts are now being made by the health authorities of these States to stamp out the disease, and the orders recently issued by the State Board of Health of Illinois, if systematically enforced, ought to produce a marked change in the small-pox reports from this State within the next month.

These orders do not enforce compulsory vaccination, although the Board has the legal right to do so, but they urge it in the strongest terms and suggest that local boards may properly treat persons refusing to be vaccinated as suspects, especially if they have been in any way exposed to the contagion of the disease.

The circular of the Illinois Board concludes as follows: "*No disease can be so surely prevented or controlled as small-pox. Its existence in a community argues carelessness or ignorance.* The latter may be pardoned in immigrant laborers and peasants; *either is inexcusable in any American citizen.*" Making some allowance for the rhetoric of this statement, it fairly expresses the views of physicians and sanitarians of the present day, and it may therefore be taken for granted that the present epidemic proves that there are in this country a large number of persons unprotected by vaccination. These may be divided into two classes. The first includes those who have never been vaccinated, and is mainly composed of adult foreigners and negroes and of young children of all classes for whom the operation has been omitted through carelessness and forgetfulness. There are a few cases in which the omission has been deliberate through fear of evil results from the operation itself, but the number of these is so small that it is unnecessary to take it into account in relation to the epidemic.

The second class includes those who are supposed to be vaccinated, but who are really unprotected, either because the true vaccinia was never developed in them, or because it was developed insuffi iently or imperfectly, or in some few cases, as in some cases of persons who have suffered from small-pox itself, there seems to be a sort of perpetual susceptibility to the disease.

We shall notice here but a single cause of this insufficient vaccination, and that is the difficulty of getting fresh, pure, and thoroughly reliable virus. This difficulty is, it is true, very small; it really involves only the obtaining a post-office order and writing a letter; but, small as it is, it is no doubt often sufficient to turn the scale by causing the matter to be put off for a more convenient hour until it is totally forgotten. One remedy for this, and probably the most effectual one which can be devised, is that the virus shall be furnished gratuitously to physicians by the State under the guarantee of the inspection of a skilled inspector as to its purity and power.

This is done by the State of Maryland, but the guarantee is probably not of much value, for the State has under its control no establishment for the production of bovine virus. Whether a National vaccine farm should be established under the direction of the National Board of Health, for the purpose of supplying reliable bovine virus to all physicians needing it, is a question which is now being discussed to some extent.

It is probable that this is the only way in which a gratuitous supply of such virus can be provided, since it is almost certain that few, if any, of the individual States will undertake such a task; and while there are some objections to it, we think that, upon the whole, Congress would act wisely in authorizing and directing the Board to try the experiment.

So far as regards quarantine regulations, it seems to us that every emigrant to this country should either show satisfactory evidence of good vaccination, or be vaccinated.

It will, of course, be useless to attempt to enforce this regulation at all points on either the Canadian or Mexican frontiers, for a permanent land quaran-

tine along such extended lines is practically impossible, but far the larger number of emigrants enter at our great sea-ports, where such a vaccination regulation can be carried out with comparative ease.

With regard to methods of dealing with the disease when it has appeared in a community, we may have something to say hereafter.

AMERICAN MEDICAL LITERATURE.

IN the NEWS of the 7th inst., we quoted from the London *Medical Times and Gazette*, the assertion that "American medical literature is very voluminous, and characterized by great originality, inventive genius, industry, and practicality." It would be difficult to convey higher praise in the same number of words, and so eulogistic an opinion from an English critic whose position gives him ample opportunity of forming a correct judgment, ought to be sufficient to encourage those among us who are laboring in the cause of medical science, and to silence the croakers who are blindly seeking for some external cause to explain the deficiency which they assume to exist. While they are thus wasting their energies, and waiting for the good time when fame and wealth shall be had without labor, the real live men in the profession have been earnestly at work, and have already built up a literature which commands respect throughout the scientific world.

No observer who has reached middle life can have failed to note the change which has taken place in this regard within the narrow compass of a single generation. The time is not so long past when the few eminent writers of whom we could boast—Dewees, Wood, Dunglison, Meigs, Hodge, Drake, Bigelow, Mott, and their compeers—were little known beyond our own shores; when students had few text-books of home production, and the medical issues from American presses were largely composed of reprints. Now, however, our men of mark are known, and quoted with respect wherever the language is read; there is scarcely a subject on which the student cannot find at least one excellent American work eminently adapted for practical use; and the proportion of reprints among the publications of the day is yearly growing less. American medical science is asserting its right to be heard, and the assertion is listened to with constantly increasing respect. The future, indeed, is bright. As the English language is becoming the dominant one among civilized men, and as America is becoming the leading nation of the earth, it is a world-wide audience to whom our writers will speak through the press. Already in far-off Australia, New Zealand, and Japan, they have their attentive disciples, and these will multiply, together with the teeming millions at home and in the fatherland, into a multitude which will stimulate to yet higher exertions the best minds among us.

In the natural exultation which such a prospect is well-fitted to call forth, we should not forget the debt which we owe to our English brethren. If we are relying upon their labors less now than we did a generation ago, the aid which they afforded us, when we were not as self-sufficing as we now are, was substantial indeed. Their works, unsurpassed in practical value by those of any other race, were reprinted in this country, and the humblest student was thereby enabled to avail himself of their teachings; and to this free communication of their ripest professional experience we doubtless owe the training of many minds which have since become teachers in their turn; to it we certainly owe the stimulation of the reading habit which gives to our own writers their circle of readers. Even the editing of these books, and adapting them to the wants of the American reader, which has so long formed a favorite theme for the criticism of the unthinking, has been an essential service, rendered in many cases by leading men in the profession, who have thus, in addition to the benefits conferred on the student, aided in fitting themselves for subsequent independent work.

All this has been accomplished in the absence of an international copyright law, which many have assumed to be an essential condition precedent to the growth of a flourishing home literature. Yet notwithstanding this, the development has been healthy and rapid—quite as rapid, indeed, as that of any other country. The influence of international copyright, however, is a subject requiring more space than we can devote to it at present, and we hope to recur to it at an early day.

There is one peculiarity in the existing condition of our medical literature, to which we may properly call attention. This is the fact that most of our writers of books are residents of Philadelphia or New York. This is, of course, partly attributable to the fact of the superior clinical and educational facilities of the larger centres of population, where the material for research and observation is at hand, and the stimulus to work is greater, from the activity of medical teaching, and the attrition of mind with mind. Partly, also, it is to be explained by the attraction which these great cities exert upon those who distinguish themselves elsewhere. Gross was a resident of Louisville, Flint and Hamilton, of Buffalo, and Bartholow, of Cincinnati, when they laid the foundation of their fame as writers by works which proved their power as thinkers and teachers. Yet, after due allowance made for these causes, we cannot but think that the eminent men who are to be found scattered among the profession everywhere throughout our country, have not been diligent enough in discharge of the duty, which they owe to themselves and to

their generation, not to allow the results of their studies and of their experience to die with them. Much of this may doubtless be accomplished by journalistic contributions—much already is done in that direction—but much more can be done, and one of the leading aims of the NEWS will be to stimulate the production of this material, and to give it the widest circulation among the readers of that English race which now encircles the globe.

ABDOMINAL SURGERY.

MR. LAWSON TAIT, in a recent issue of the *Medical Times and Gazette*, gives a very interesting summary of his last year's experience in Abdominal Section. From November 1, 1880, to November 1, 1881, he opened the abdomen either for definitely-determined and successfully-accomplished operation, or for exploration, 110 times, of which 51 were cases of ovariotomy. Of the whole number, 9 (8.2 per cent.) died; and of the ovariotomies, 2 (3.49 per cent.). He repudiates entirely the antiseptic system. But the thing that strikes one most forcibly is the utterly different position held by the peritoneum to-day as contrasted with its autocracy of twenty or thirty years ago. Then it was *noli me tangere;* now the danger is, that opening the peritoneal cavity may become almost a morning's amusement to rash and inexperienced men. Then ovariotomists, certain of their diagnosis, and of the possibility of the removal of such tumors, were denounced in unmeasured terms and with the most offensive epithets; now exploratory operations, undertaken deliberately to find out what is wrong in doubtful cases, "serve the purpose of complete tappings, and as the patients uniformly recover, they do no harm at all." The lesson the gynecologists have taught, the surgeons should not pass by, as, in fact, Billroth and Sims, Péan, Czerny, Simon, and others, by their brilliant operations on the stomach, the gall bladder, the spleen, and the kidney, have shown us. The female peritoneum resents injuries perhaps no more quickly than the male, nor in cases of ovarian tumors more than in ileus or abdominal wounds. An exploratory operation, with our present surgical knowledge and methods, is not only no more dangerous than an intussusception, or a bullet in the belly, or a stab that may have produced unsuspected hæmorrhage or other unknown damage, but is, in fact, far less dangerous. Lawyers not infrequently assert that no class of men are more timid under public responsibility than doctors, and especially surgeons in medico-legal cases. If true (and to some extent it is), it is not to be wondered at in view of the constant attempts of our "brothers-in-law" to lay the death of the patient in such cases as Fiske's and Landis's and many others to the doctor rather than the assailant. But now that the way has been clearly pointed out, and its dangers shown to be far less than we had supposed, we should not be slow to seize upon our advantages. The next ten years should show as great an advance in our general surgical treatment of abdominal lesions by abdominal section as has the last ten in gynecological practice. Mr. T. Smith some time since asked whether the peritoneum might not be treated after strangulated hernia, followed by peritonitis, as after ovariotomy, by opening the abdominal cavity, and washing it out; but the profession has not yet answered his question. But when we remember that Battey's operation, the extirpation of the kidney (of which Dr. Thomas gave a notable case in our issue of January 7), splenotomy, the extirpation of the entire uterus, cholecystomy, and exsection of a part of the stomach, are but of yesterday, it is hard to predict what feat to-morrow may not see successfully accomplished.

VETERINARY MEDICINE.

A NEW avenue is likely to be opened in this country for the labors of those energetic and praiseworthy philanthropists, the members of the Society for the Prevention of Cruelty to Animals. An ordinance has just been introduced into Select and Common Councils of Philadelphia looking to the purchase by the University of Pennsylvania of a lot of ground adjoining the present college buildings, and intended chiefly for the establishment of a veterinary school and hospital, in which the diseases of our domestic animals can be studied, taught, and treated.

The condition of veterinary medicine in the United States is by no means creditable to our humanity, enterprise, or business foresight. Capital, usually so sensitive in such respects, is here phenomenally indifferent to the safety of large investments. The aggregate value of the live-stock of the country, including poultry, is not less than $2,000,000,000, and is probably more. Serious epidemics, or, rather, epizootics, have from time to time broken out, and have raged uncomprehended and unchecked, destroying immense numbers of valuable animals. The pleuro-pneumonia of New England cattle in 1859; the Texas fever of 1868; the influenza, which in 1872 affected a large majority of the horses of the Eastern States; the foot-and-mouth disease, which, after establishing itself here, fortunately died out, but proved so serious in England; the various appearances of murrain, hog-cholera, chicken-cholera, and other similar ailments, some of which carried off a majority of the animals attacked—all these are instances of the insecurity in this country of property held in horses, cattle, sheep, swine, or poultry.

With the incompetency of the average veterinary surgeon to deal not only with these but with minor and every-day disorders, we are most of us familiar, and, indeed, in the majority of cases, treatment is relegated to the groom or blacksmith, the shepherd, drover, or cowleech.

But as an example of the beneficial results following *scientific* work in this relation, it may be mentioned that M. Pasteur, of Paris, has recently discovered that, by a process of inoculation closely resembling vaccination, poultry can be protected from chicken-cholera, and cattle and sheep from *anthrax*. Within the last few weeks it is said that 30,000 animals have been inoculated at his laboratory, and it is proposed to extend this protective influence to all the cattle in France.

So far as we know, there is but one organized school of veterinary medicine in America, and of late years but little has been heard from that, probably on account of the lack of public support and patronage, of which we have reason to believe it was thoroughly deserving. Charters have several times been granted by State Legislatures, twice in Pennsylvania, once in Massachusetts, and once in New York, but with the single exception mentioned without subsequent results.

Abroad veterinary medicine has existed as a distinct science for one hundred and twenty years. Schools have been established at Lyons, Paris, London, Glasgow, and Edinburgh, and many of them are in a flourishing condition. Students are compelled to pass a preliminary examination, and a course of three years is compulsory before a license to practice can be granted. In the large cities, successful practitioners of this branch of medicine frequently earn professional incomes of from $5000 to $8000 per annum.

In England and in Scotland, the veterinary surgeons have formed corporate bodies under royal charters, which empower them to appoint examining boards, and to confer diplomas or certificates, which, we are told, are "fully recognized as a guarantee of professional ability by the public throughout Her Majesty's dominions, as well as by the authorities at the Horse Guards and at the India Office."

Any movement in this direction in this country should appeal, it seems to us, to a wide range of sympathies, and should at once enlist in its behalf several large classes of public-spirited citizens; the humanitarians, because to limit and prevent animal suffering is even better than to relieve it, and because the cases of disease immeasurably outnumber those of cruelty or neglect; the capitalists, because by wide-spread diffusion of knowledge on this subject, large amounts of property will be thereby rendered more secure from loss or fluctuation; the political economists and legislators, because a new field of work and profitable employment will be opened up to hundreds of our young men, and because a serious annual loss of national wealth will, in all probability, be greatly lessened or altogether prevented.

PUBLIC ABATTOIRS.

THE establishment, under sanitary surveillance, of abattoirs or public slaughter-houses, in Boston, New York, Philadelphia, Baltimore, and Chicago, is an evidence of proper appreciation of the principles which should govern local sanitary administration. Still other cities are considering the propriety of introducing this much-needed reform, among them Charleston, S. C. A committee appointed to make an investigation of the subject, has examined into the details of these establishments in several of the places above mentioned, and, from personal observation and inquiry, has unanimously concluded to report in favor of the project. This result might have been anticipated, since an unprejudiced investigation must show that the concentration of the entire business of slaughtering and of the utilization and disposal of refuse in well-apppointed and well-regulated buildings, under strict sanitary inspection, is far preferable to the old plan, which permitted the work to be conducted without regulation, except so far as it suited the convenience or caprice of the individual proprietor, and not unfrequently to the annoyance of a whole neighborhood. In addition to the avoidance of nuisances so generally resulting from tardy and careless utilization of the refuse from slaughtering, there is the great advantage which the abattoir system affords of systematic inspection of meat, whereby an additional protection is extended to the public. Charleston is to be congratulated on this progressive movement, and other cities beset with the same annoyances would do well to follow her example.

THE FEES OF THE MEDICAL ADVISERS OF THE LATE PRESIDENT.

A NEWSPAPER report, which has obtained considerable prominence, is to the effect that the Congressional Committee appointed to audit the expenses of President Garfield's illness will insist that the attending and consulting physicians shall present itemized bills duly sworn to with affidavits that the charges are reasonable and usual.

Putting aside altogether, as beneath notice, the implied doubt as to the integrity of those gentlemen, it is manifestly improper that services of such an extraordinary character should be estimated at the usual rates for professional attendance. When distinguished surgeons in active and extremely lucrative practice relinquish their personal occupations, throw aside all other engagements, and

devote themselves almost exclusively to the consideration of a particular case, it is evident that ordinary rules as to "visits" and "consultations" must be set aside in the endeavor to form a just estimate of the value of their labors.

If their services had been voluntary, or in any way pressed upon the patient or the nation, there might be just cause for a display of economy in their remuneration, but under existing circumstances, their constant attendance having been insisted upon by Mrs. Garfield and by members of the Cabinet, we fail to see how Congress, through its committee can, with justice, take any but the broadest and most liberal action in the matter.

It is just, too, that those gentlemen already in the government service, should receive some substantial recognition of their faithful, devoted, and certainly altogether extra-official efforts in behalf of the distinguished sufferer.

In view of the facts we have mentioned, and, in addition, of the hurried and peremptory summons which were repeatedly sent, the frequent and exhausting journeys, not altogether devoid of danger, the stupendous mental strain and anxiety involved in the management of a case of such unprecedented importance, and the almost total cessation of all other occupation, and consequently of ordinary revenues, the Committee would reflect discredit upon itself, and fail to represent the sentiment of the nation, if it offered, as has been suggested, a pecuniary recompense based upon the ordinary professional fees of the average practitioner.

It is safe to say, that the customary fee of a surgeon or physician of eminence called from New York or Philadelphia to Washington, simply to express an opinion upon a case of sufficient gravity to warrant his presence, would not be less than from $800 to $1000, and that he would expect to receive at least $300 daily if he were detained there.

BEEF-TEA AND URINE.

IT is rather a novel idea that in taking a cupful of beef-tea we are really drinking what is equivalent to a cup of urine. According to Mr. Masterman, however, who not long since published a chemical analysis of beef-tea, the two are as alike as may be, only that urine appropriately contains more urea and uric acid. And now comes Dr. Neale, of London, who has been, apparently, in the East Indies, and not only assures us that urine is used as a vehicle for (less agreeable?) medicines, but that, "as a stimulant and general pick-up, I have frequently seen a glass of a child's or a young girl's urine tossed off with great gusto and apparent benefit."

Reduced to straits, we presume we might so use it, but we confess that, usually, "as a stimulant and general pick-up," we mightily prefer the other form of the cup that cheers but does not inebriate.

THE MEDICAL REGISTRATION ACT.

THE law, enforcing the registration of all physicians practising in Pennsylvania, enacted by the last Legislature, was doubtless intended as a first step towards such legislation as may be necessary to secure to our citizens competent medical advisers. As might be expected when such interests are to be provided for and conciliated, the law passed contains some unwise provisions, is obscure in its wording, and admits of various intepretations. That legislation is needed to correct the abuses of medical practice, is conceded by all, but there is no uniformity in the methods of relief proposed.

The present registration law is a transcript nearly of the New York Act, which is now enforced in that State—a fact which ought to silence those who complain that our law was contrived by the medical colleges of Philadelphia. That provision which requires graduates of medical schools in other States to submit their diplomas for verification to one of the medical faculties of this State. is an exact reproduction of the New York law. The medical faculties are required not only to decide as to the genuineness of the diploma, but "to satisfy themselves as to the qualifications" of the applicant, after which "they shall direct their Dean to endorse the diploma." Two interpretations have been given to this provision of the law. The most obvious construction, sanctioned, also, by eminent legal authority, is, that the person presenting himself with the diploma of a school in some other State or country, and demanding its endorsement in conformity with the terms of the law, must "satisfy" the faculty by passing a proper examination. Such an examination, followed by an official endorsement of the diploma, is equivalent to the usual examination for the doctorate, and the subsequent attestation of the candidate's fitness by the signatures of the faculty on his diploma. The holder of a foreign diploma is thus granted another and even more authoritative evidence of professional qualification. It could hardly be expected that the faculties would give so much time and labor, without compensation, and we hold that the schools of New York and of Philadelphia who had proposed to fix a fee of twenty dollars for this service, did not exceed their proper rights. At the same time we are bound to state on undoubted authority that the Philadelphia schools have not received any fees from candidates.

The other interpretation of the Act, which is equally sanctioned by eminent legal opinion, is, that the faculty may be "satisfied" by proof of the identity of the person named in the diploma, and of the

genuineness of that instrument. Without being subjected to a professional examination, the qualifications are assumed on the possession of the diploma, and the Dean certifying these facts to the Prothonotary, the individual is allowed to register. No fee is exacted for this service. We learn that the medical faculties of Philadelphia now base their action on the latter interpretation of the law, and assume that the possession of a genuine diploma from a reputable school is proper proof of professional qualification. We learn, further, that the medical schools of this city are organizing an effort to have this section of the law modified. They regard it as offensive and unjust for the faculty of a medical school in this State to sit in judgment on the qualifications of a medical man, attested by the signatures of a faculty in good standing in another State. Restrictions on diplomas bounded by State lines are manifestly improper. A diploma granted by a reputable medical college should be of equal value in all the States.

PREVENTION OF SMALL-POX.

WE once heard a military officer speak of a great railroad as a great civilizer, and there is no question as to the correctness of the designation. From the centralization of power, possessed in the United States by corporations alone, they are able to accomplish with comparative ease that which municipal, legislative, and even Congressional effort has less power to do thoroughly. This is instanced in the case of the Pennsylvania Railroad, whose action upon the subject of color-blindness we had occasion to record last week. The same company, as we are informed, now requires from each laborer in its employment, and we presume the same rule applies to all grades of employés, a certificate of proper vaccination from some reputable physician. Certainly a most admirable as well as most efficient manner of settling the subject of compulsory vaccination, and one worthy of consideration by all employing large numbers of men and women. Were the same rule established and rigidly adhered to by all employers, much would be accomplished towards stamping out variolous disease.

Such action as that referred to above is not only directly preservative, so far as the laboring classes are concerned, but it must do much in making public opinion. Were such action imitated in factories and workshops throughout the land, it would perhaps make vaccination fashionable, and even the scientific medical mind cannot dispute the controlling power of fashion.

TREATMENT OF BOILS.

DR. LOWENBERG finds incisions and boracic acid solution the most effective treatment of boils. Holding that they are produced by a microphytic parasite, he rejects the usual emollient treatment. He commences by incising them, after the application of ether spray, and then foments with a saturated aqueous or alcoholic solution of boracic acid. When the boils are recent, and the patients refuse the permission to incise them, he finds that simple fomentations with boracic acid solution arrests the development of the inflammatory process.

It may be added that certain internal remedies possess a high degree of value in a succession of boils, notably the pyrophosphate of soda, and the hypophosphites. The relation of a succession of boils to a saccharine condition of the urine should not be overlooked. This is an unknown cause sometimes of their persistence in spite of all the usual remedies.

SPECIAL ARTICLE.

THE PRESENT EPIDEMIC OF SMALL-POX IN THE UNITED STATES.

AFTER having been almost entirely absent from the mortality reports of our large cities for several years, small-pox reappeared at the end of the year 1879 in Philadelphia, New York, and Washington, with an evident tendency to spread. Previous to this it had existed for several months in Texas, and especially in San Antonio. Little or nothing is known as to the mode of its introduction, the outbreaks in Washington and Philadelphia being especially mysterious as to their origin, but it had been prevailing in Canada, Mexico, Austria, Barbary, and Paris, and it probably reached this country from several distinct sources. During the year 1880, the disease became diffused throughout Europe, and especially in European Russia, Austria, Italy, and Germany, although it nowhere assumed the proportions of an epidemic. At the beginning of the year 1881, the principal focus of the disease was in Philadelphia, in which city 196 deaths from small-pox were reported in the month of January. A second centre existed in New York City, a third in Brownsville, Texas, a fourth in Chicago, and a fifth in San Francisco, and from these points and from fresh importations by emigrants, it has gradually spread until, at the end of the year, it existed in almost every State of the Union.

The city which suffered most severely during the year was Philadelphia; the total number of deaths from this disease reported in this city during 1881, being 1319. Six hundred and fourteen of these occurred during the first quarter, the highest number of deaths reported in any one month being 215 in March.

In Chicago, during the year, there were 822 deaths from small-pox, the highest number in any one month being 166 in October, and the next highest, 141, in December. New York City reports 453 deaths from this disease during the year, the highest number in any one month being 84 in June. In

Pittsburg the disease has progressively increased throughout the year, reaching a maximum of 125 deaths in December.

The following table, compiled from the weekly reports contained in the *Bulletins of the National Board of Health*, shows the number of deaths from small-pox reported from the principal cities in this country throughout the year.

Cities and Towns.	Population.	Deaths in 1881.				
		First Quarter.	Second Quarter.	Third Quarter.	Fourth Quarter.	Total.
Boston, Mass	362,535		1		7	8
Fall River	49,006	1	1			2
Westfield	7,587			3		3
Holyoke	21,851				15	15
North Adams	10,192	1				1
New Bedford	26,875				1	1
Gloucester	19,329				1	1
New Haven, Conn	62,822		1			1
New Britain	13,978	2				2
Meriden	18,340	3				3
New York, N. Y	1,206,577	97	196	73	87	453
Brooklyn	566,689	7	11	9	7	34
Poughkeepsie	20,207	1				1
Amsterdam	11,711	6				6

Total		951	895	743	1411	4000

Although this table contains only the reports from the principal cities, and gives no information in regard to smaller towns or villages, or rural districts, it is sufficient to show very clearly the wide-spread prevalence of the disease. We have no means of ascertaining the total number of deaths from this cause in the United States during the year, but it is safe to say that it is more than four thousand. It is impossible to obtain any reliable data as to the number of cases represented by this mortality; nor can the number of cases be calculated by the number of deaths reported with any degree of accuracy, inasmuch as the death-rate may be stated to range from 1 to 20 per cent. of those attacked, depending upon previous vaccination and the general character of the epidemic. In Manchester it has been calculated that each death from small-pox represents sixteen seizures of the disease. In Chicago, during the past year, it is estimated that there have been about two thousand (2000) cases, which would give a mortality of over 40 per cent. It is probably safe to say that the total number of cases in the United States during the year is over twenty thousand (20,000).

The principal spreading of the disease has been along the lines of immigration, and the greater number of cases have occurred among foreigners unprotected by vaccination. In Chicago it is stated that, owing to the enforcement of the rule requiring those children who attend the public schools to present certificates, signed by practicing physicians, that they have been vaccinated, there have been but seven school children attacked with small-pox during the past five years (*Northwestern Lancet*, vol. 1, page 55).

In Cincinnati the Health Officer reports that of the first hundred cases, 33⅓ per cent. died, which would show, as in the case of Chicago above referred to, that these cases must have occurred entirely in persons unprotected by vaccination.

The disease was carried to the College of Keokuk, Iowa, by a cadaver, received from Chicago for dissection, and spread to such an extent among the medical students that the college was closed by order of the Board of Health.

Where the disease has been carried into communities methodically protected by vaccination, as is the case in many New England towns, there has been no spread, and the work done in Washington in December, 1879, is an excellent illustration of how the disease may be promptly stamped out where a community is willing to take the trouble to do it.

REVIEWS.

Die Temperatur des Gereizten Säugethiermuskels. Von Dr. Meade Smith, Arbeit aus dem Physiologischen Institut zu Leipzig.—*Arch. f. Anat. u. Phys.* Phys. Abth., 1881. pp. 105–152.

In this article, Dr. Smith reports the results of a very painstaking investigation, performed in the Leipzig Laboratory of Physiology, into the relations which exist between heat-production and contraction of the mammalian muscles. The animals employed were dogs, which were narcotized with chloral, opium, or curare. The muscles selected for study, on account of the accessibility of their nerves and vessels, were the extensors of the lower leg. The contraction of these muscles was made to record itself upon moving paper,

while thermometers, introduced into the aorta, the veins coming from the muscles and between the muscles themselves, gave information in regard to the changes of temperature in these regions. A rise of temperature in the muscles could, of course, be regarded as indicative of an increased heat-production only in those cases in which the temperature of the arterial blood was lower than that of the muscle which it supplied, for the increased vascularity of a tetanized muscle would itself cause a rise of temperature in the muscle, if the blood were warmer than the muscular tissue.

Some of the principal results of the research may be enumerated as follows:

1. The maximum temperature of a contracting muscle is independent of the load under which it contracts. This result is different from that reached by Heidenhain and Fick, in the case of frogs' muscles. The cause of the difference remains unexplained.

2. When a muscle makes an extensive contraction, its temperature rises less above that of the arterial blood than when the contraction is slight, and, in general, the connection between heat-production and contraction, though both result from the same nervous impulse, seems to be much less close in the muscles of warm-blooded than in those of cold-blooded animals.

3. The persistent shortening of a muscle after the stimulation has ceased (known to German writers as "contractur"), resembles tetanus, in the fact that when it is overcome by a heavy load, the muscle returns to its former contracted condition on the removal of the load; but it differs from tetanus in the rapid diminution of temperature by which it is accompanied.

4. Tetanus lasting less than two minutes, causes in muscles deprived of circulating blood as high a temperature as can be produced in muscles in which the circulation is going on.

5. Experiments on curarized muscles give no support to the view that nerve stimulation may cause heat-production without muscular contraction.

In the course of the experiments, it became evident that many of the questions which arose required calorimetrical observations for their solution. An investigation of this sort upon excised muscles supplied by an artificial circulation, seems to Dr. Smith within the possibilities of physiological experimentation.

It is to be hoped that he may be able to continue his studies in this direction, and thus throw additional light upon the problems discussed in his present valuable paper.

A SYSTEM OF SURGERY, THEORETICAL AND PRACTICAL. IN TREATISES BY VARIOUS AUTHORS. Edited by T. HOLMES, M.A. Cantab., *First American from Second English Edition, thoroughly revised, and much enlarged*, by JOHN H. PACKARD, A.M., M.D., assisted by a large corps of the most eminent American Surgeons. In three volumes. Vol. II., 8vo, pp. 1063. Philadelphia: Henry C. Lea's Son & Co., 1881.

The second volume of Holmes's Surgery follows fast upon the first, and gives hope that the work will be speedily completed by the appearance of the last. The present volume treats of the Organs of Special Sense, the Circulatory, Digestive, and Genito-Urinary Organs. The increase in the number of the illustrations we notice again is very large, being about 150 per cent. of additional cuts. The articles are of a character that allows of additions much better than those in the first volume; there is less need of re-casting them. Thus, in Diseases of the Bladder, eight pages are given to Bigelow's operation of Litholapaxy by Dr. Keyes. In Diseases of the Teeth, Dr. Truman has wisely obtained from Dr. Kingsley, a section of six pages on Obturators in Cleft Palate, while Dr. Skene has added over ten pages bodily (chiefly from Thomas and Emmet) on Lacerations of the Perineum and of the Cervix Uteri, and an important and entirely new chapter of forty pages on Injuries and Diseases of the Absorbent System, by Dr. S. C. Busey, has been added. We can add little to the favorable opinion expressed when noticing the first volume. The editors have done their work well, and very few errors or omissions of the original have escaped them. The mechanical execution of the work, except some of the wood-cuts, is excellent, much better than in the first volume.

SOCIETY PROCEEDINGS.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, January 6, 1882.

GEORGE ROSS, M.D., PRESIDENT, IN THE CHAIR.

Pneumonia, Diphtheritic Gastritis.—Dr. OSLER exhibited the specimens, which were taken from a man aged sixty-six, who was admitted to the General Hospital with great shortness of breath and prostration, and died in six hours. He was sent in from the House of Refuge, and the surgeon in charge, Dr. Burland, stated that he had noticed the man two days before walking about looking very blue and short of breath. He sent him to bed, and on examination the next day the signs of pneumonia were evident, and he sent him to the hospital. At the autopsy the stomach and duodenum were enormously distended with gas, the diaphragm on the left side was pushed up in front to a level with the second intercostal space. In the thorax the heart was displaced upwards and to the right, the apex being under the sternum. The right lung was universally adherent, the left was free, but pushed up and compressed by the distended stomach. The right lung was in a state of gray hepatization; the only crepitant parts were a small area at the apex and part of the lower lobe. The left lung was small, compressed, but feebly crepitant. The stomach presented an area of diphtheritic inflammation 12 x 10 cm., just to the left of the cardiac orifice. The mucosa of this region was deeply injected and covered with a closely-adherent grayish-white false membrane, from one to two mm. in thickness. When stripped off, the membrane beneath was deeply congested and rough. In the centre of the patch was a spot from which it had been removed. In the vicinity of the large area were other small bits of false membrane on congested bases. Œsophagus and duodenum normal.

Dr. Bristowe, of St. Thomas's Hospital, was the first to describe diphtheritic inflammation of the alimentary canal in pneumonia; he met with it in the colon in two out of thirty secondary, and in four out of sixteen primary pneumonias. Dr. Osler, in about fifty autopsies in primary pneumonia, had met with five instances of croupous or diphtheritic colitis. This was the first specimen in which the stomach was affected. In connection with this, he called attention to the frequency of the so-called diphtheritic endocarditis in pneumonia; thirty-eight per cent. of the cases which he had analyzed occurred with inflammation of the lungs. The extreme distention of the stomach had probably taken place during life and in connection with the gastritis; it doubtless assisted in bringing about the fatal termination by embarrassing the heart and compressing the healthy lung.

The PRESIDENT remarked on the latency of pneumonia in old men, and on the special liability of these cases to sudden death from heart failure.

Mitral and Tricuspid Stenosis.—Dr. MOLSON related the case—a woman aged thirty-nine, who died in the hospital after a residence of four days. She had had rheumatic fever when nine years of age, and ever since had been troubled with short breath and cough on exertion. The chief symptoms on admission were dyspnœa, extreme rapidity and irregularity of the heart, scanty urine, albuminous, and with granular casts. There was no dropsy. Nothing positive could be determined as to the character of the murmurs under an aggravation of the symptoms; the woman sank on the fourth day. Dr. Osler presented the specimens. The heart showed extreme mitral stenosis, with great thickening of the fused segments; left ventricle small, walls of average thickness; left auricle dilated and hypertrophied. The tricuspid orifice admitted the index-finger, the segments of the valves had united, and the edges were thickened. The right ventricle was dilated and hypertrophied; the right auricle much dilated. The lungs were universally adherent; pleura at left apex very thick, and for an inch or more the lung tissue beneath it was cirrhosed, and had dilated bronchi and fibrous bands passing through it. The lungs were in a state of brown induration, but not congested. The kidneys were slightly reduced in size, granular and rough on the surface, and in a state of tolerably advanced cirrhosis.

Dr. OSLER, in reply to a question by Dr. T. W. Mills, stated that he thought the condition of the kidneys might have been the outcome of the chronic valve disease, and represented a later stage of the large indurated organs commonly met with. There was not extensive arterial disease or hypertrophy of the left ventricle.

The Brains of Criminals.—Dr. OSLER read a paper on this subject, and recorded the results of an examination of the brain of the murderer Hayvern, who was executed at Montreal on the 11th of December. He first referred to the observations of Benedikt, of Vienna, who, in eighty-seven hemispheres from forty-four criminals, has found certain peculiarities which he regards as indicative of a lower type of cerebral organization. The points upon which he most dwells are the confluence of many of the principal fissures, and the existence in a considerable proportion (twenty-seven of the eighty-seven) of four frontal gyri, the fourth being formed by the splitting of the first or second gyrus. This is regarded as an animal similarity.

Hayvern was a low, dissolute fellow, addicted to drink, with no special neurosis in his family, who, on June 29, stabbed a fellow-convict. The brain weighed forty-six and a half ounces, and was fairly well formed; the cerebellum was completely covered by the cerebrum. On examination, it was found to conform in many respects to Benedikt's cases, and was atypical, according to his views, in the following particulars: The union of the Sylvian fissure with the first frontal gyrus; the junction of the interparietal with the parieto-occipital and first temporal fissures; the extension of the calcarine fissure into the scissura hippocampi; the union of the collateral and calcarine sulci, and in the fusion of the first frontal gyrus, so that there appeared to be four frontal convolutions arising from the ascending frontal or anterior central gyrus.

To ascertain how far these peculiarities existed in the brains of hospital patients, Dr. Osler examined forty-three hemispheres from twenty-four individuals, and found that a very considerable proportion were of the confluent fissure type. Thus, the Sylvian fissure joined the fissure of Rolando in eight hemispheres, the frontal sulci in eighteen, the interparietal in nineteen, the first temporal in twelve. The chief difference between Benedikt's series of brains of criminals and those examined, was a greater number of unions between the typical fissures, more particularly the fissure of Rolando, which in the former joined contiguous sulci in twenty-four instances. In nine of the forty-three hemispheres, there were four more or less distinct frontal gyri. He thought that much fuller information was needed about the arrangement of the sulci in the different races, and many more criminals would have to be examined before any positive result was arrived at as to the constant atypical character of the brain in members of this class. Speaking of Benedikt's conclusions, he questioned whether it was wise to speak of criminals as an anthropological variety of their species. On his views there is no place left for responsibility; but society cannot afford to have a class of criminal automata, and every rascal pleading faulty gray matter in extenuation of his crimes.

Dr. HENRY HOWARD (Med. Supt. Longue Pointe Asylum) asked if it were known how many of the brains in the series of hospital cases were from criminals, and whether a larger proportion presented abnormalities than could be reasonably thought to belong to this class. He believed in a criminal class as distinct as a mercantile class, and regarded the mental and moral condition of the individuals belonging to it as dependent absolutely on their physical organization. Hayvern was not responsible for his act; it was not premeditated, but performed under the influence of an uncontrollable impulse; and he thought that there was evidence to show that it may have been connected with the epileptic neurosis.

Dr. HINGSTON wanted to know how it was, if viciousness and crime were the product of defective cerebral organization, that some notoriously wicked men had reformed and lived sober and honorable lives? Was it probable that with such a change there was any alteration in the structure of the brain?

Dr. CAMERON thought that, for Benedikt's conclusions to have any value, it must be shown that criminals have invariably atypical brains, and all other people normal ones. Most criminals have some degree of control over their actions, and the law is an effectual deterrent in many instances, particularly where the penalty enacted touches the person. He illustrated the rapid abolition of garroting by the introduction of the lash, and quoted facts to show the good effects of capital punishment.

Dr. SHEPHERD remarked that it was somewhat difficult to say what was the typical brain. The majority of observations were upon the lower classes; we lacked data as to the arrangement of the fissures and convolutions in a large number of the intellectual members of society. He had frequently seen brains of the confluent fissure type in the dissecting-room.

Dr. MILLS said that, with reference to the series of brains from hospital patients examined by Dr. Osler, the question arises as to how far such patients belong to the criminal class. In about one thousand that he had observed closely, he did not think that many of them ranked in this class.

Dr. OSLER, in reply to Dr. Howard's question, stated that the series of brains which he had examined were nearly all preserved by Giacomini's method, and no data existed from which the social status of the individuals could be ascertained. In the forty-three hemispheres (nineteen perfect brains and five halves), nineteen presented one or more atypical features.

Tiemann's "Urethral Finder."—Dr. HINGSTON showed an instrument, lately made by Tiemann, for facilitating the finding of the urethral canal when a number of false passages existed.

Foreign Bodies in the Windpipe.—Dr. HINGSTON narrated two cases. *False tooth in the trachea for over three months, tracheatomy, removal.* The patient, an elderly lady, who had worn a false incisor tooth for over forty years, and had never been in the habit of removing it at night, noticed one morning that she could

not find it. After searching in vain for some time, her attention was directed to a suspicious cough, and she began to think she might have swallowed it; though she had not been disturbed during the night and had no remembrance of its dropping into the throat. When she consulted the doctor, there was very little inconvenience, no difficulty of breathing; but while in his house a violent paroxysm of coughing came on, and she appeared to be choking. Brunelle's method of inversion was at once practised, and she was relieved. An operation was urged and consented to, but the following day she felt so well that she refused to submit. Dr. Hingston heard nothing more of her for several weeks, when she came again, the cough having become troublesome. She again refused operative measures. After consulting several other medical men, all of whom assured her that the tooth was in the windpipe and must be removed, she returned to Dr. Hingston, and finally decided to have the operation performed. On Nov. 1st, the trachea was opened, and with a pair of slightly curved laryngeal forceps the offending tooth was readily grasped, being situated in the neighborhood of the orifice of the right bronchus. It was a small incisor, with a flat gold plate and two lateral extensions to fasten it to the contiguous teeth. It was coated with dark mucus. In the operation, Dr. Hingston adopted a device which answered admirably. After a long incision through the skin and superficial fascia, he made a transverse incision just below the cricoid, inserted the director upon the trachea and tore down, with the greatest ease and without any bleeding, the tissues covering the first five or six rings. The remarkable feature about the case was the length of time the foreign body existed without producing very serious inconvenience.

Dr. HINGSTON, in response to a question from the President, stated that he thought there was some little difficulty to the entrance of air into the right lung.

The second case was that of a young boy, son of a farmer in New York State, who had had *a pin in the windpipe for eleven months*. A day or so after swallowing it, the child was brought to Dr. Hingston, but, as there were no special symptoms, an operation was not deemed advisable. The child subsequently suffered a great deal from cough, fever, and expectoration. He would be better at times, and then severe fits of coughing would come on. One day, after riding on a comrade's neck, he had an unusually hard coughing spell, and ran to his mother, who put him across her knees and struck his back forcibly. Shortly after he went out to the door-step, and while coughing put his finger down the throat and drew out the pin. He has since been quite well.

Chloral Poisoning.—Dr. CAMERON reported a case of a lady who took one hundred and sixty grains of chloral hydrate at a single dose, for suicidal purpose. When seen three hours after, the pulse was eighteen, the pupils contracted, features pale. Believing that the chief indication was to support the failing heart, chloric æther. ♏xxx, was injected subcutaneously every half-hour for four doses, with marked improvement of the pulse and general symptoms. Emetics were employed, but very little came up in the vomiting. The patient made a good recovery.

Dr. PROUDFOOT mentioned that in Boston, when chloral first came into use, he gave sixty grains an hour, for six hours, to a man with delirium tremens. No dangerous symptoms followed; so far as he knew, the drug was good, having been imported from Germany.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, January 5, 1882.

E. L. DUER, M.D., PRESIDENT, IN THE CHAIR.

Extra-uterine Fœtation. — Dr. WILLIAM GOODELL reported the case of Mrs. B. C., aged thirty, who had been married two years without conceiving, but on March 19 her catamenia ceased, and she deemed herself pregnant. She now began to suffer very much from nausea and from pelvic pains, for which her physician, Dr. W. C. Parry, of Mount Holly, N. J., was in attendance more or less after May 6. On May 16, while ironing, she was suddenly taken with a violent colicky pain in her right groin, accompanied by a vaginal flow of blood and by collapse. These colics lasted off and on up to July 15, when she felt relieved. Dr. Parry had in the meantime discovered a pelvic tumor on the right side of the womb, and had diagnosticated extra-uterine fœtation. But from September 5 to 13 she had great bearing-down pains, like those of labor, attended by some hæmorrhage. The cervical canal dilated sufficiently to admit the finger; a miscarriage seemed imminent, but nothing was thrown off. This threw the physician off his track, and he renounced the idea of extra-uterine fœtation for that of natural pregnancy. She had felt fœtal movements, but from this time the child was still and milk appeared in the breasts.

Her health now began unaccountably to fail, she lost flesh and strength, and became bed-ridden. During the first week of last November, she had another hæmorrhage, with labor-like pains, and the cervical canal and os externum again dilated during the disturbance. From this time she began to fail very rapidly, having chills, a high temperature, a frequent pulse, and quick emaciation. On November 15, I was called in to see her. On account of the excessive tenderness of the parts, ether was given. An irregular tumor occupied the abdomen, but smaller than the uterine globe at eight months' gestation; neither fœtal limbs nor the fœtal outline could be felt, nor could the presence of any fluid be made out. The cervix uteri was in a natural position, quite hard, and with a small os externum. The sound passed in five inches, and to the left. No fœtal sounds or uterine murmur could be detected. My diagnosis was a guarded one, but leaned to an extra-uterine gestation. On November 24, aided by Dr. B. F. Baer, of Philadelphia, and by Drs. W. C. Parry, A. E. Budd, and R. E. Brown, of Mount Holly, I performed the operation of laparotomy. As soon as the peritoneum was cut open, an adventitious cyst was exposed. I perforated it with a probe, and enlarged the opening with a uterine dilator. Finding that the placenta covered the whole lower three-fourths of the sac, I prolonged the opening upwards and removed the fœtus. It was macerated, and had been dead some time, as the flesh over the ribs was stripped off during the process of extraction. The placenta was now very slowly and carefully stripped off without any hæmorrhage; every preparation had been made to meet one. Not any liquor amnii was present. The sac was then thoroughly cleansed with a carbolated solution, and every antiseptic precaution taken. The opening in the sac was stitched to that of the abdomen; a glass drainage-tube put in, and the wound dressed with salicylated cotton. Up to December 9 everything went well. The wound united perfectly, the stitches were taken out, the temperature had fallen, and the drainage-tube was about to be removed, when near midnight she very unaccountably went into convulsions; these recurred, and she died comatose on the morning of the 12th. Albumen was found in the urine, and at an autopsy the kidneys were found to be diseased. The fœtal sac had become obliterated, and no relation whatever could be discovered between the condition of extra-uterine fœtation and that of the kidneys which carried her off—the latter seemed to be an accident, and in nowise related to the former. From the history of this case, there is no question, in my mind, that the operation of laparotomy for extra-uterine fœtation must be far more successful after the death of the child. For when the

child is living, it would, on account of the inevitable hæmorrhage, be unjustifiable to remove the placenta; and the presence of so large a mass, which must slough off and putrefy, will seriously compromise the life of the woman. But when the child has been dead for some time, the placenta can be safely peeled off and the sac be wholly emptied, as in my case.

A Successful Case of Hysterectomy.—Dr. GOODELL also reported the following case. The patient, a mulatto of thirty-five, had cystic degeneration of each ovary. The pelvic and intestinal adhesions were of the most formidable character, making in themselves a long and a bloody operation. But in addition to these complications, each ovary was so incorporated with the womb that he was obliged to remove that organ. This he did by dissecting off the bladder, by applying the wire-clamp at a point midway between the os externum and the os internum, and by transfixing the stump with two pins. Strange as it may seem, on the fourth and fifth days quite a smart menstrual flow, or rather a metrostaxis, took place from this small cervical fragment. The clamp fell off on the fourteenth day, leaving a very large and deep funnel-shaped opening, which is now rapidly filling up. It is now three weeks since the operation, and the patient is convalescent. He stated that ovarian tumors are rare in the colored race, this being the second case, only, which he had seen. On the other hand, fibroids of the womb and fibrocystic tumors are more common with them than with the white race.

Monocyst probably of the Ovary, but which Contained Limpid Fluid.—Dr. B. F. BAER exhibited a specimen with the following history: M. J. T., aged forty, single, catamenia regular. In October, 1880, she discovered an abdominal tumor in the centre of the hypogastrium. She has been growing thin in flesh with the growth of the tumor. It apparently has varied in the degree of tension, being sometimes more flaccid than at others. Physical examination revealed a cyst of the abdomen, not very tense, extending one hand's-breadth above the navel; the cervical resonance was very marked, dulness on percussion was also marked, and there was perfect fluctuation throughout the tumor. The womb was movable, flexed to the right, and lay behind the tumor. The sound passed three inches. From the flaccidity of the cyst, I was at first inclined to believe it to be a cyst of the broad ligament; but the rapid growth of the tumor, and the quick emaciation of the patient, pointed rather to an ovarian cyst. On Dec. 31, 1881, the tumor was removed by Prof. Goodell. It was found to occupy a position to the left of the uterus, and was at first thought to be a cyst of the broad ligament, for the following reasons. It was a thin-walled monocyst, and contained a perfectly limpid fluid. The Fallopian tube was stretched over the surface of the tumor and elongated, the fimbriæ were spread out on the wall of the cyst. But after a very careful search the ovary could not be found. In a cyst of the parovarium, the ovary usually occupies a position on the side of the tumor, more or less closely attached to it by a mesovarium. After the pedicle had been ligated and the tumor cut away, another careful search was made for the ovary, both in the pelvis and on the cyst, but it was not found. The right ovary was found in the normal position, and was healthy. The only portion of the cyst-wall which in any way resembles the remains of a degenerated ovary, is a dense white substance, corresponding in position to that which would probably be occupied by the ovary; but this forms part of the cyst-wall, as the tunica albuginea does in ovarian cystic disease, and there is no sign of an attachment by a mesovarium.

The interest in this specimen hinges on the organ from which it was developed. If it could be proven that it originated in the parovarium, then it is of no special interest, because the arrangement of the external and middle coats allows them to be readily separated from one another, and the Fallopian tube is related to the cyst-wall in the manner described by Dr. Bantock as peculiar to parovarian cysts; the fluid furnished by it also corresponds to that usually found in such a cyst. But if it is a monocyst of the ovary, it then becomes of special interest, for it is denied by several recent writers (Bantock and Tait, for instance) that monocystic tumors ever occur in the ovary, but that when such a cyst is found it is always of parovarian origin. Now that seems to be too sweeping a statement, for many eminent authors, among them Wells, Peaslee, and Atlee, speak of having met with unilocular ovarian cysts; and I can recall a case of a large monocyst, removed by Dr. Goodell from a young lady of twenty years, in which the history, the relative position of the Fallopian tube to the cyst-wall, the close adherence of the different coats to one another, the albuminous fluid rich in cells, and the absence of the ovary, pointed pretty clearly to ovarian disease rather than to parovarian.

I also present another specimen, which proves beyond a doubt that a monocyst may occur, at least while the cyst is small. This specimen was removed by Dr. Goodell from a lady twenty-two years of age. It presents a single cyst in each ovary, and, in addition, a cyst in the broad ligament of one side.

Again, if the specimen first exhibited originated in the ovary, it presented an unusual feature in the character of its fluid, which was limpid and devoid of cells. If it did not spring from the ovary, why could not that organ be found? It could hardly be congenitally absent, when all the organs in its neighborhood—Fallopian tube, broad ligament, and parovarium—were present.

Dr. GOODELL did not consider this cyst one of the ovary, simply because the corresponding ovary could not be found, for one cannot make a prolonged search at such a time. Besides, he had never seen such a clear fluid from an ovarian cyst. Again, another diagnostic point of a broad ligament cyst is the alternations of tenseness and flaccidity; so this cyst was sometimes quite tense and at others so relaxed as to make it quite difficult to define its outlines. An ovarian cyst, on the contrary, is always tense, even if it has been recently tapped, but refilling. Further, the peritoneal and other layers of the wall of an ovarian cyst are so firmly matted together by the cicatrices made by the escape of Graafian follicles, that they cannot be easily separated. In this specimen the layers are, like those of a parovarian cyst, very easily torn apart. He himself had no doubt that the cyst is one of the parovarium.

Dr. T. M. DRYSDALE believed that a thorough search of the cyst might disclose the presence of the ovary, as he had, in several cases of tumor of the broad ligament, discovered the missing ovary spread over and incorporated in the cyst-wall. He also considered the limpid fluid, free from cells, an incontrovertible diagnostic point.

NEW INVENTIONS.

A NEW ASPIRATOR AND STOMACH-PUMP.

Feeling the importance of the more general distribution of such a useful and necessary instrument as the aspirator, and believing that the great costliness of the present instrument is the main obstacle to its more general use, Dr. GEORGE T. MILLER, of Byronsville, Ga., has, with the assistance of Messrs. George Tiemann & Co., of New York, been able to devise such an instrument as, is hoped by its cheapness, will remove this

hinderance, and by its effectiveness and simplicity meet with general favor.

The instrument is made of hard rubber in the main. The metallic portion is nickel-plated. 1. Pump. 2. Flexible tube with glass tube inserted, used for exhausting. 3. Needle. *a*. Stopcock. *b*. Nozzle for attachment of exhaust tube. *c*. Nozzle for attachment of escape tube. *d*. Thumbscrew for working stopcock, *a*.

To use the instrument attach one end of tube 2 to the selected needle and the other to nozzle, *b*. Attach a piece of tubing to nozzle, *c*, for conducting pus, etc., to a suitable vessel, and then, after introducing the needle, turn the thumbscrew, *d*, in the line, *a*, *b*, and then draw out the piston; when the pump is full turn the thumbscrew, *d*, in the line, *a*, *c*, and shove down the piston. This action may be repeated as often as necessary. If desired the needle can be attached directly to point, *b*. It will be perceived that this instrument can very readily be used for injecting a solution into a cavity, as well as evacuating its contents, by simply reversing the action of thumbscrew, *d*.

It can also be used as a stomach-pump, and with one of George Tiemann & Co.'s soft-rubber "velvet-eyed" stomach tubes it is always ready for an emergency, and very effective. And further, it can be used for any purpose that a Davidson syringe can, if only the proper tubes are attached to nozzle, *b*, all of which are obtainable from the makers, Tiemann & Co.

Dr. Miller claims that this instrument is equally effective as the most costly; that it is less liable, from its simplicity of construction, to become disordered; that from its low price, it is within the reach of all practitioners, and that from its extended uses it fulfils a long-felt desideratum.

NEWS ITEMS.

BALTIMORE.

(*From our Special Correspondent.*)

Physiology of the Isolated Mammalian Heart.—At the Johns Hopkins University, Professor Martin is continuing his experiments on the physiology of the isolated mammalian heart. His method of procedure is as follows, viz.: A cannula is put into each common carotid trunk, and another into the left subclavian. The right subclavian is ligated, as is also the aorta immediately beyond the origin of the left subclavian. In this way, all flow through the systemic arteries, except the coronaries of the heart, is prevented. Next, the inferior cava is tied just above the diaphragm, and then the azygos vein; a cannula connecting with a reservoir of fresh, warm, defibrinated blood is tied into the vena cava descendens close to the heart. Blood from the reservoir is supplied to the right auricle, and, simultaneously, bleeding is carried on from the cannula in the right carotid, until all the blood originally contained in the heart and lungs of the animal (dog) is washed out and replaced by defibrinated blood. The animal is then transferred to a warm, moist chamber, kept at a uniform temperature of 37° C. by an automatic gas regulator. In this chamber are two Marriott's flasks, filled with warm, defibrinated blood; their outflow tubes unite in a common tube, which is attached to the cannula in the vena cava descendens. From the Marriott's flasks the heart is supplied readily with fresh blood, under a uniform pressure and at a constant temperature. So soon as one is empty, its outflow tube is closed and that of the other opened, so that the experiment goes on for hours without interruption. The cannula in the left carotid of the dog is connected with an outflow tube supplied with a stopcock; the latter is opened so far as to permit a certain proportion of the blood which has entered the right auricle, traversed the lungs, and been expelled by the left ventricle into the aortic arch to flow out into a beaker; the rest of the blood, propelled by the heart, must pass through the vessels of that organ, no other way being open. The cannula in the left subclavian is connected with a mercurial manometer, whose pen records arterial pressure and pulse-rate on the paper of a kymograph in the usual manner. Uniform artificial respiration is maintained by a small water engine.

In this way, the heart of the dog or of the cat may be kept alive for hours (in one case for seven hours), beating with perfect regularity, and maintaining a normal arterial pressure. All this time there is no circulation in any other organ of the body, but the lungs; brain, spinal cord, and sympathetic, die within a short time, and the muscles pass into a state of rigor. The heart and lungs are completely physiologically isolated. With uniform artificial respiration, the influence of the lungs upon the heart is constant throughout an experiment. An artificial lung is, however, in course of preparation. Professor Martin has recently completed a series of experiments relating to the influence of variations of arterial pressure upon the rhythm of the heart-beat. A rise of arterial pressure when the pneumogastrics are intact, is known to slow the pulse-rate by excitation of the medullary cardio-inhibitory centre; and after the vagi are cut, to quicken it, indirectly, by stimulating the medullary centres of the accelerator nerves of the heart. When all extrinsic cardiac nerves are divided, the results obtained by different experimenters vary in every conceivable way. Some find that higher arterial tension quickens the pulse; others, that it slows it; and some, that it has no effect; others again find all of the above three different results in different experiments. The reason of this diversity is not far to seek; the methods employed to vary arterial pressure (compression of the thoracic or abdominal aorta, or injection of blood from another animal into an artery of the experimental animal), change many things besides arterial tension; for example, rate of inflow to the auricle, pressure in the veins opening into the auricle, and hence in the right auricle itself, temperature of the blood, and chemical composition of the blood. All these secondary effects having been ignored, the origin of contradictory results of previous workers is readily seen. In Professor Martin's experiments, blood is supplied, under uniform pressure and at uniform temperature, to the right auricle. Arterial pressure is varied by opening or closing the stopcock on the outflow tube from the left carotid. The artificial respiration being uniform, arterial pressure is the only condition changed under these circumstances. He finds that within physiological limits, variations of

arterial pressure have not the slightest direct influence upon the pulse-rate. In small dogs, pressure in the subclavian may be varied from one hundred and sixty to twenty millimetres of mercury, and the number of heart-beats per minute remains absolutely unchanged. An increase or decrease of arterial pressure *per se*, has no effect on the pulse rhythm. When the variations of arterial pressure are so great as to become pathological, then changes in the heart's rate follow them. For example, if arterial pressure (measured in the subclavian), is kept for a moment at about fifteen millimetres of mercury, then not enough blood is driven through the coronary arteries to nourish the heart, and its beat becomes slower. On the other hand, if the exit stopcock be nearly closed, and the inflow to the right auricle be considerably increased, more blood reaches the left ventricle in its diastole than it can force out during its systole, through the narrowed aperture of the stopcock, and through the coronary arteries, the only paths open. The heart-beat, then, is profoundly modified; it becomes markedly slowed and dicrotous, a powerful systole, apparently half emptying the ventricles and being immediately followed by a less marked beat, which is succeeded by a pause before the next powerful systole occurs. The defibrinated blood referred to, has been in most cases simply whipped and strained blood from other dogs; in some cases, of late, this has been diluted with one-third its bulk of a 0.7 per cent. solution of pure sodium chloride in distilled water, with satisfactory results. Quite recently, defibrinated calf's blood has been used, with success, to nourish the isolated dog's heart. Professor Martin is at present engaged in investigating the action of varied pressure in the veins opening into the right auricle, and of varied temperatures upon the pulse-rate of the isolated mammalian heart. Two of his students are studying the action of digitalin upon it. Dr. Sewall, associate in physiology, is studying the influence of pneumogastric stimulation upon the isolated mammalian heart, with varied pressure in the right auricle. This line of research will, doubtless, lead to very important results.

CINCINNATI.

(*From our Special Correspondent.*)

ADULTERATION OF SUGAR.—The local societies are well attended this winter; numerous papers have been presented, and the discussions which followed them have been full of interest.

The winter session of the Academy of Medicine was opened by a paper by Dr. James G. Hyndman, which consisted of a report on the examination of samples of white sugar for muriate of tin, the agent so often employed in the bleeching process. Six different specimens of sugar—representing the product of four refineries—were examined, and all with negative results. The presentation of this paper led to a more general discussion on adulteration of various staple articles of food.

PREVENTION OF LACERATION OF THE PERINEUM.—Dr. Thad. A. Reamy recently delivered an address before the Academy of Medicine on his new method of preventing laceration of the perineum. He prefaced his remarks by a brief reference to the anatomy of the parts, and an account of the various means hitherto employed in the attempts to prevent laceration. His own plan consists in placing the patient on her back in the usual forceps position (the limbs being flexed to the greatest degree practicable), and stretching smoothly over the patient's bulging perineum a towel, the extremities of which are held beyond the gluteal masses on either side by his own or his assistant's hands. The perineum is not touched except by the towel, and all the tension is made from the ends of the towel. Applied smoothly in this manner, with its upper border on a level with the posterior commissure, and the posterior border extending to a point opposite the coccyx, the towel forms a supplementary perineum, which, while remaining untorn, effectually prevents rupture of the tissues beneath. The doctor had tested his plan thoroughly in private practice, and had also demonstrated its utility in a recent case of forceps delivery before his class at the college. He was perfectly assured of its effectiveness, and recommended resort to it in cases of forceps delivery, and in other cases, especially in primiparæ when any disproportion existed between the size of the head and the vulvar orifice. The plan is also applicable in the prevention of laceration by the shoulders, and the towel should not be removed until after their delivery.

MONTREAL.

(*From our Special Correspondent.*)

LAVAL UNIVERSITY.—The Laval University question, which has excited so much interest here for the last three years, has been at last settled by decrees from Rome. The point at issue was, briefly, this: Laval, at Quebec, is the only Catholic university in the province, and is in the hands of the more liberal section of the clergy. The French Canadians in Montreal have long wished for another university, but have never been able to get the consent of the church authorities. In 1876, Laval decided to establish a branch (succursal) in Montreal, with full faculties, and as there was already a French medical school, arrangements were made to take over its teachers as professors in the medical faculty; indeed, the names were printed. At the last moment the agreement was annulled, and the majority of the teachers in the L'École de Médecine decided to stand by the old institution, and have nothing to do with Laval. A number of the active members of the school remained firm to their agreement with Laval, and a medical faculty was organized. The contest has been chiefly between these rival schools; the old L'École de Médecine, backed by a large section of the Montreal clergy and several bishops, has contested the legality of the Laval branch, as her charter defined her location at Quebec. In this they had the support of Sir Farrar Herschel, the Solicitor-General of Great Britain. An act was obtained in the local Legislature, extending the Laval charter so as to cover the Montreal branch. But the real struggle has been at Rome, to which both parties appealed, and to which deputations have been sent. The latest news is that the sacred congregation has finally decided in favor of Laval. Our French brethren are faithful sons of the church, and settle their disputes in a good old mediæval way. The Laval faculty at Montreal has been very energetic. A good school-building has been procured, and a new hospital established (Hospital de Notre Dame), as the Hotel Dieu is entirely under the medical control of the L'Ecole de Médecine.

LIBRARY OF THE SURGEON-GENERAL'S OFFICE.—From the annual report of the Surgeon-General we learn that nearly 2500 volumes and 3200 pamphlets have been added to the library during the past year, making the total number about 54,000 volumes and 60,200 pamphlets.

The publication of Volume II. of the *Index Catalogue* has been completed, and the edition of 1500 copies is being distributed. The manuscript of Volume III. is now going to press. An estimate has been forwarded for printing Volume IV. of the *Catalogue*, and it is hoped that the appropriation asked for will be

granted, in order that the progress of this important work may not be retarded.

It is earnestly recommended by the Surgeon-General, and by the President in his message to Congress at the commencement of the last session, that an appropriation be made for a new fire-proof building, adequate for the present needs and reasonable future expansion of these valuable collections. Such a building, absolutely fire-proof, it is believed could be erected for $250,000.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.—The annual meeting of the College was held on Wednesday evening, January 3, when the following officers were elected for the ensuing year: President, Dr. W. S. W. Ruschenberger; Vice-President, Dr. Alfred Stillé; Secretary, Dr. R. A. Cleemann; Treasurer, Dr. Charles S. Wurts.

Dr. Stillé, Chairman of the Library Committee, reported that the total number of volumes in the library was 22,419, of which 16,405 belonged to the general library, 6014 to the Lewis library. The total increase during the year was 1040 volumes.

UNIVERSITY OF PENNSYLVANIA.—The Provost of the University, Dr. William Pepper, has petitioned the Councils of Philadelphia to transfer to the University, for a nominal sum, the tracts of land belonging to the city, and lying adjacent to the present University site for the erection of a school of veterinary science, and a hospital for domestic animals, dormitories, museums, training-school for nurses, and free library.

The trustees agree in return to devote the property entirely to educational purposes, to maintain fifty scholarships for students from the public schools of Philadelphia, and to pay an annual ground-rent to the city, or principal sum in lieu thereof. The petition and the proposed ordinance, with a strong recommendatory letter from the Mayor, were referred by Councils to the Committee on Finance and City Property, which has since reported unanimously in their favor.

Ground has been broken for the Henry C. Gibson Ward for Incurables, and it is believed that this addition will be ready for occupation next summer.

NEW HAMPSHIRE DISTRICT MEDICAL SOCIETY.—The annual meeting of this Society was held at Concord last week, Dr. George Cook, Vice-President, in the chair. Papers were read by Dr. George H. Sanborne, Dr. Fowler and Dr. Walker. Dr. Watson, Secretary of the Board of Health, made some remarks concerning drainage.

The following officers were elected for the ensuing year: President, Dr. George Cook; Vice-President, Dr. D. P. Goodhue; Secretary, Dr. George C. Blaisdell; Treasurer, Dr. H. M. French.

The next meeting will be held in April.

PRESBYTERIAN HOSPITAL, PHILADELPHIA.—The Trustees of this hospital have just authorized the formation of a dispensary service for diseases of the ear, and have placed it in charge of Dr. Charles H. Burnett, well known as the author of an excellent systematic work on the diseases of the ear. It is proposed to utilize this service for the purposes of clinical instruction.

A NEW COLLEGE OF PHARMACY.—The Governors of Union University have organized a department of pharmacy, to be known as the "Albany College of Pharmacy." The lecture-rooms and laboratories of the Albany Medical College will be used for the purposes of the college of pharmacy. The course of instruction is graded, and the faculty consists of Dr. Jacob S. Mosher, Professor of Botany and Materia Medica; Willis G. Tucker, M.D., Professor of Chemistry; Gustavus Michaelis, Professor of Pharmacy.

THE WARREN TRIENNIAL PRIZE.—The Warren Prize Committee offer a premium of $400 for the best dissertation worthy of a prize, upon the following subject: "Chronic Bright's Disease (parenchymatous and interstitial nephritis); the Nature and Mutual Relations of the Disturbances of the Circulatory and Secretory Organs." Dissertations should be forwarded to the Resident Physician, Massachusetts General Hospital, Boston, on or before February 1, 1883.

MEDICAL EDUCATION.—The Report of the U. S. Commissioner of Education states that during the year 1879 the degree of Doctor of Medicine was conferred by "regular" Colleges (68 in number) on 2759 candidates. During the same year there were in the United States eleven training schools for nurses, with 51 instructors, 298 pupils, and 141 graduates.

THE MISSOURI MEDICAL COLLEGE has organized a post-graduate school, with a faculty of thirteen, composed in part of the members of the regular faculty, and in part of distinguished specialists, not members of the faculty. The course covers the whole range of practical medicine. It begins February 20, and will continue for six weeks.

HEALTH IN MICHIGAN.—The State Board of Health, in its *Bulletin* for the week ending January 7, states that the reports indicate that bronchitis and influenza increased considerably, and that erysipelas, tonsillitis, and puerperal fever decreased considerably, in area of prevalence.

Up to date, small-pox is reported at Detroit, Bay City, Grand Rapids, Kalamazoo, South Haven, and near Monroe. A new case was brought to Grand Rapids from Chicago, January 9. Vaccinations are general in many parts of the State.

THE PARIS FACULTY.—Prof. VULPIAN resigned on the 17th of November the position of Dean of the Faculty of Medicine of Paris, a position which he has held since December, 1875. A vote of thanks for his past services and regret at his resignation was unanimously passed by his colleagues. Prof. Béclârd has been nominated as his successor.

It is understood that owing to the appointment of M. Paul Bert to be Minister of Public Instruction, Prof. Vulpian considered that the period of his usefulness as Dean of the Faculty had come to an end.

CONSULTATIONS WITH HOMŒOPATHS.—The Royal College of Physicians of London have adopted the following resolution without a dissenting vote:

"While the College has no desire to fetter the opinion of its members in reference to any theories they may see fit to adopt in connection with the practice of medicine, it nevertheless considers it desirable to express its opinion that the assumption or acceptance by members of the profession of designations implying the adoption of special modes of treatment is opposed to those principles of the freedom and dignity of the profession which should govern the relations of its members to each other and to the public. The College therefore expects that all its fellows, members, and licentiates will uphold these principles by discountenancing those who trade upon such designations."

Suffice it to say that Dr. Wilks, in moving the resolution, said it was not directed against *opinions*, but against quackery, which he defined as trading in treatment, homœopathy being, therefore, the "quintessence of quackery."—*Lancet*, Dec. 31, 1881.

DEATHS UNDER ETHER.—In recent numbers of the *Lancet* (August 27 and September 3), there are reported two more deaths under the administration of ether; in one case, that of a woman of fifty, who was being operated on for the removal of a tumor from the jaw, death could be attributed to collapse from profuse hæmorrhage and interference with breathing from cancerous deposits in the lungs, which, however, were only revealed by the post-mortem examination. At the inquest, it was decided that death resulted from the effects of the operation, but that "said operation was in all respects skilfully and properly performed." In commenting on this case, the *Lancet* advises that when an operation is about to be performed, in which the danger from suffocation is increased by the operation itself, it is safer, all things being taken into account, to administer a quickly-acting anæsthetic, like methylene, rather than ether, and that in all diseases of the lungs, the anæsthetics of the chlorine group are safest and best.

The second case can more properly be called a death *from* ether. The patient was a miller, aged forty-eight, and the operation was consequent upon the patient having run a rusty bill-file into the middle finger of the right hand. The patient had suffered from rheumatism, but the heart was normal. Under the administration of ether, and before the patient was anæsthetized, respiration suddenly ceased. Artificial respiration was resorted to, but without avail. The verdict at the Coroner's inquest was death from syncope, but the *Lancet* believes that the death in this case also can be attributed to the lungs, which were supposed, in the absence of any evidence, other than the man's occupation, to be emphysematous. In this case, also, it believes that methylene would have been a safer anæsthetic, or even local anæsthesia might have been employed.

The *Medical Times and Gazette*, for December 24, reports the death of a laboring man, sixty-seven years of age, who died while being etherized, from the entrance of blood into the trachea from a compound wound of the jaw. The operation proposed was the suturing of the bone fragment with wire.

M. PASTEUR'S VACCINATIONS.—Statistics brought up to October 1 show that the inoculations of splenic fever, according to Pasteur's method, were performed on 160 flocks, comprising 68,900 sheep, of which 33,576 were vaccinated, and 21,938 animals were left uninoculated, so as to judge of the results of the difference of treatment. Before vaccination, the losses caused by splenic fever amounted, on the whole of the flocks, to 2986 animals. During vaccination, and until its effects were perfected, 260 sheep out of the whole number of 33,596 perished. During the same period, the mortality rose to 366 out of the group of 21,938 which were not vaccinated. When the effects of vaccination were complete in the first group, the mortality from splenic fever fell to five. This rate has persisted up to the present time; and the next statistical account will give, it is expected, the same satisfactory results as regards the groups of animals vaccinated and left unvaccinated.—*British Med. Journ.*, Nov. 19, 1881.

COHN ON THE EYES OF MEDICAL STUDENTS.—Dr. Cohn (*Med. Jahbr. d. K. K. Gesell. d. Aerzte. z. Wien.*, 1881), says that fourteen years ago he found that 53 per cent. of the Catholic theological students, 55 per cent. of the law students, 56 per cent. of the medical students, 67 per cent. of the Evangelical divinity students, and 68 per cent. of the philosophical students, were myopic. In the summer of 1880, 59 per cent. of the medical students were myopic, 55 per cent. of the junior or non-clinical students, and 64 per cent. of the advanced or clinical, the longer studies of the latter being probably the cause of the higher percentage. In discussing the cause, Cohn says that the blame lies entirely upon the methods of study. The lecture halls are badly lighted, the benches and desks so arranged as to make writing most uncomfortable and difficult, the type of the text-books is too small, and the lines too long (straining accommodation when the eye passes from the ends to the middle), as well as too closely printed. He recommends that the light should fall fully on every spot in hall; that the benches should be 45 centimetres (17.7 nches) high, and 40 centimetres (15.8 inches) broad, while the desks should be 70–75 centimetres (about 29.5 inches) high, and 35 centimetres (13.8 inches) broad, to allow of easy writing. The type, he says, should be 1.5 millimetres (.06 inch) in size—of small *n* for example—and 0.25 millimetres (.01 inch) in thickness of line; the intervals between the lines should be at least 2.5 millimetres (.1 inch), and the lines should not exceed 100 millimetres (about 4 inches) from one side of the page to the other.—*London Med. Record*, Nov. 15, 1881.

ALBUMEN WATER is recommended as a good substitute for milk and beef-tea, in cases where these substances disagreed with the patient, or could not be obtained. The preparation is largely used by the French. It is made by dissolving the white of one or more eggs in a pint or two of water, sweetening with glycerin, and flavoring with orange-flower water. It may be taken cold and used *ad libitum*. It is an excellent food in typhoid fever and typhoid dysentery.—*Dublin Journ. of Med. Science*, Sept., 1881.

A GASTROSCOPE.—Dr. MIKULICZ, of Vienna, has perfected an instrument by which the interior of the stomach and œsophagus are submitted to direct inspection by means of an incandescent platinum electric light in a metal œsophageal tube. The instrument is described in the *Allgemeine Wien. Med. Zeitung*, Nov. 8, 1881.

LITHOLAPAXY IN EGYPT.—At the meeting of the Société de Chirurgie, held on December 7, reported in *Le Progrès Médicale*, December 10, 1881, M. Zancarœ read a long and interesting report of eighty-one cases of calculus, treated by different methods, in the Greek Hospital at Alexandria. M. Zancarœ gives decided preference to the Bigelow method, which he employed in fourteen cases.

A PAY HOSPITAL FOR WOMEN.—The experience of those connected with "The Seaside House for Invalid Women," at Atlantic City, has shown that there is greatly needed a pay hospital for women in moderate circumstances, who do not need and would not accept the assistance of the charitable.

The success of "The Seaside House" encourages the belief that a hospital for this class of women could, with a moderate rate of board, be made nearly if not quite self-supporting. The institution has most of the appliances needed for such a hospital, and instead of allowing them to remain idle during nine months in the year, it has been determined, as an experiment, to keep the house open this year.

Application for admission should be made to Dr. Bennett, No. 332 South Fifteenth Street, Philadelphia.

MEDICAL CONGRESS AT SEVILLE.—A medical Congress will be held at Seville, commencing April 9, 1882, lasting, for scientific discussion, until the 16th.

The transactions of the Congress will be published in the *Gaceta Medica de Seville*.

PERSONAL.—Prof. Freund, of Strasburg, has been offered the Chair of Obstetrics in Breslau, vacant by the

death of Prof. Spiegelberg, and has, it is reported, accepted it.

In the recently-published number of this *Archiv*, Prof. Virchow has published a letter of thanks to all who took part in the recent demonstration in his honor. He regrets that he is unable to thank each personally; but he is convinced that the expressions towards him were heartfelt, and to each one he returns his most cordial thanks.

NEW JOURNALS.—The first number of the *New England Medical Monthly*, under the editorial direction of Wm C. Wile, M.D., appeared in the latter part of last year; it is a fifty-page octavo journal with a well-filled table of contents, and presents an attractive appearance. It is published in Newtown, Conn.

The first number of the *Detroit Clinic*, a new weekly medical journal, which appears to derive its support from the Detroit Medical College, has been issued with the date of January 4, 1882. It is a neatly-printed octavo of sixteen pages of text.

The *Rocky Mountain Medical Review* has, on account of the removal of Dr. A. W. Adams from Colorado, been merged into the *Rocky Mountain Medical Times*, a handsome monthly journal, under the editorship of Drs. T. H. Hawkins and F. A. E. Disney.

NOTES AND QUERIES.

CONGENITAL BRONCHOCELE.

To the Editor of the MEDICAL NEWS.

SIR: Has there ever been any notice or record of congenital bronchocele on this continent? All that I know of it in Europe, is the notice given it by Prof. Hartshorne in Reynold's *System of Medicine*, where he notices its occurrence in France and Derbyshire, England.

I had a well-marked case of it in this city, where the disease is not common and only sporadic. There could be no mistake about the diagnosis, as the case was plain. There was no history of heredity. Parents of good form; tall, young, handsome, intelligent, and of long-lived stock. Mother, fourteen months previous, in her first labor, at seven months, I delivered by severe force of a frog-like monstrosity.

The child, in this last accouchement, was a girl, otherwise well formed, and healthy. The tumor, which was large and produced so much deformity that it created much sadness in the household for a time, gradually disappeared, and was not noticeable after a few weeks. Two kinds of applications were made with gentle pressure. One composed of turpentine spirits, camphor, and iodine in glycerin; and another, ergot and glycerin. The tumor was soft, and seemed to be highly vascular.

I am, sir, yours, etc.

M. R. MORDEN.

ADRIAN, MICH.

[Congenital bronchocele is undoubtedly a very rare malformation, but it has been observed.—ED.]

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 4, TO JANUARY 16, 1882.

TREMAINE, W. S., *Captain and Assistant Surgeon.*—Now awaiting orders in New York City, to report in person to the commanding general, Department of the East, for assignment to duty.—*S. O. 2, A. G. O., January 4, 1882.*

POWELL, J. L., *First Lieutenant and Assistant Surgeon.*—The seven days leave of absence granted him in order 186, Fort Stockton, Texas, is extended fifteen days.—*O. 159, Department of Texas, December 27, 1881.*

CARTER, W. F., *First Lieutenant and Assistant Surgeon.*—The seven days' leave granted him by order 195 c. s., Fort Concho, Texas, extended one month, providing he furnish an acceptable substitute during his absence, without expense to the United States.—*S. O. 160, Department of Texas, December 29, 1881.*

GORGAS, WM. C., *First Lieutenant and Assistant Surgeon.*—The leave of absence granted him by Par. 5, S. O. 150, Headquarters Department of Texas, December 3, 1881, is extended one month.—*S. O. 1, Military Division of the Missouri, January 4, 1882.*

MADDOX, THOMAS J. C., *First Lieutenant and Assistant Surgeon.*—Now awaiting orders in Washington, D. C., to report in person to the commanding general, Department of Texas, for assignment to duty.—*S. O. 2, A. G. O., c. s.*

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FROM OCTOBER 1, TO DECEMBER 31, 1881.

HEBERSMITH, ERNEST, *Surgeon.*—Relieved from duty at San Francisco, Cal., and placed on waiting orders, November 7, 1881. Relieved from waiting orders, November 26, 1881.

VANSANT, JOHN, *Surgeon.*—Granted fourteen days' leave of absence, October 18, 1881. To proceed to San Francisco, Cal., and assume charge of the service at that port, November 8, 1881.

MILLER, T. W., *Surgeon.*—Granted leave of absence for seven days, October 6, 1881.

PURVIANCE, GEORGE, *Surgeon.*—To proceed to Boston, Mass., and assume charge of the service at that port, November 8, 1881.

AUSTIN, H. W., *Surgeon.*—To proceed to Galveston, Indianola, Corpus Christi, and Brownsville, Texas, as Inspector, October 17, 1881.

FISHER, J. C., *Passed Assistant Surgeon.*—To proceed to Yorktown, Va., as Inspector, October 14, 1881. Detailed as member of Board for the examination of keepers and crews of the Life-Saving Service, Third District, November 18, 1881.

GOLDSBOROUGH, C. B., *Passed Assistant Surgeon.*—Detailed as member of Board for the examination of keepers and crews of the Life-Saving Service, Fifth and Sixth Districts, November 2, 1881.

O'CONNOR, F. J., *Assistant Surgeon.*—Granted leave of absence for fifteen days on account of sickness, December 23, 1881.

GUITERAS, JOHN, *Assistant Surgeon.*—Granted leave of absence for ten days, December 5, 1881.

BENSON, J. A., *Assistant Surgeon.*—Granted leave of absence for twenty-one days, December 7 and 21, 1881.

BANKS, C. E., *Assistant Surgeon.*—To assume temporary charge of the service at San Francisco, Cal., until the arrival of Surgeon Vansant, November 7, 1881.

CARMICHAEL, D. A., *Assistant Surgeon.*—To proceed to Baltimore, Md, for temporary duty, November 2, 1881. To rejoin his station (New York), and thence proceed to Pittsburg, Pa., and assume charge of the service at that port, November 18, 1881.

BENNETT, P. H., *Assistant Surgeon.*—To proceed to Boston, Mass., for temporary duty, October 21, 1881.

PECKHAM, C. T., *Assistant Surgeon.*—To report for temporary duty to Surgeon-in-charge, Boston, Mass., October 21, 1881. To proceed to Vineyard Haven, Mass., for temporary duty, November 4, 1881. To rejoin his station (Boston), and thence proceed to New York, reporting for duty to Surgeon-in-charge, November 9, 1881.

AMES, R. P. M., *Assistant Surgeon.*—To proceed to St. Louis, Mo., for temporary duty, October 21, 1881. To proceed to Evansville, Ind., for temporary duty, December 24, 1881.

DEVAN, S. C., *Assistant Surgeon.*—To proceed to San Francisco, Cal., for temporary duty, October 21, 1881.

URQUHART, F. M., *Assistant Surgeon.*—To report for temporary duty to Surgeon-in-charge, New York, N. Y., October 21, 1881.

APPOINTMENTS.—The following candidates, having passed the examination required by the Regulations, were appointed Assistant Surgeons, by the Secretary of the Treasury, October 20, 1881:

PHILO H. BENNETT, M.D., of New York; CYRUS T. PECKHAM, M.D., of Massachusetts; ROBERT P. M. AMES, M.D., of Pennsylvania; SPENCER C. DEVAN, M.D., of Missouri; and FRANCIS M. URQUHART, M.D., of New York.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

CARTWRIGHT LECTURES.

ON THE EXPERIMENTAL METHOD IN MEDICAL SCIENCE.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, January 24, 1882.

BY JOHN C. DALTON, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

LECTURE I.

GALVANI AND GALVANISM IN THE STUDY OF THE NERVOUS SYSTEM.

MR. PRESIDENT AND GENTLEMEN OF THE ALUMNI: In discharging the agreeable duty, which you have kindly imposed on me, of giving the Cartwright Lectures for this year, I propose to offer a few historical sketches, which shall illustrate the manner in which certain parts of our scientific knowledge in medicine have been attained. The connection between scientific and practical medicine is, furthermore, so close that permanent improvement in the one is inseparably dependent on that of the other; but this connection becomes much more evident when we trace the history of any particular department for a considerable period of time. By this means we can see how much of the doctrine accepted by our predecessors has survived the ordeal of a century, and what were the methods of investigation which produced, in their hands, the permanent results which we enjoy to-day.

However much we may pride ourselves on the advances made during our own time, we may be sure that by far the greater part of our actual knowledge is a legacy from the past. It has been winnowed in successive generations from the errors and imperfections which always accompany its first acquisition; and it is probable that many of our own discoveries will require a similar depleting treatment in the future. But we may learn to rely with confidence on such methods of study as have heretofore proved valuable; and we may, perhaps, save ourselves the trouble of exploring certain paths, when we see that others have followed them before and have found that they lead nowhere.

If we can say that any one department in physiology, pathology, and therapeutics is now distinguished by a special activity of investigation and growth, it is probably that of the nervous system. A very large part of this advance has been made by the application of electric stimulus in determining the motor or sensitive properties of different nerves—their influence on the heart and bloodvessels, the localization of special centres in the brain and spinal cord, or the diagnosis of morbid alterations in the cerebro-spinal axis, and the use of electricity in restoring the power of movement or sensation, when impaired by disease, is now acknowledged to be, in many cases, a most serviceable means of cure. This has all come, directly or indirectly, from the experiments of Galvani, nearly a hundred years ago, on the nerves and muscles of the decapitated frog.

In 1789, Galvani was Professor of Anatomy in the University of Bologna. In addition to the regular duties of his professorial chair, he had made a number of valuable investigations in comparative anatomy; such as those on the structure of the kidneys and urinary ducts in birds, and on the organ of hearing in the same class. Like most of the scientific men of his day, he was greatly interested in the phenomena of electricity, which was then fast developing into an important department of physics. The condition of electrical science at that time was as follows: The machine, for producing frictional electricity by a rotating glass cylinder and cushion, had been brought to practical completion, and was in common use, with its prime conductor and insulating supports. The two opposite kinds of electrical excitement, known as vitreous and resinous, or positive and negative, were fully recognized, as well as the distinction between conductors and non-conductors; and even some of the phenomena of induced electricity were known, though explained in a manner somewhat different from that which is now in vogue.

Beside the electrical machine, experimenters were already in possession of the Leyden-jar, by which a large quantity of electricity may be stored in a given space; the electrophorus, by which a moderate charge of electricity may be generated; electrometers or electroscopes, for detecting the existence and amount of slight electric disturbances; and Volta's "condenser," in which small quantities of electricity, from a feeble source, might be accumulated and made apparent by the electrometer.

Finally, Franklin had shown, by his daring experiment with the kite in the thunder-storm, that the lightning of the clouds was identical in its nature with the spark from an electrical machine; and this had largely directed the attention of investigators to the study of atmospheric electricity, as compared with that produced by artificial means.

Considering the long list of results which have followed from Galvani's early observations, the manner in which they were first made is a topic of much interest.[1] He was in his laboratory, engaged on experiments with the electrical machine, and had, lying upon the table near by, a freshly dissected frog, prepared for some other purpose in such a way that the denuded hind legs were connected with the spinal column by the crural nerves. One of his assistants, accidentally touching the nerves of the animal with the blade of a scalpel, saw the legs convulsed; and on watching more closely, it was seen that the contraction occurred only at the moment of drawing a spark from the conductor of the machine.

Once Galvani's attention was attracted to so remarkable a phenomenon, his mind turned instantly to the investigation of its conditions. He abandoned all other occupations, and seemed absorbed in the attempt to detect its causes, and to learn their modes of operation. He determined in the first place that the discharge of the conductor and the contact of the scalpel with the frog's nerves were both necessary; for the muscular contractions would not take place with either of them alone. But even when both conditions were present, sometimes the muscles contracted and sometimes they did not. Puzzled by this variation, but still confident that it must have a reasonable cause, he at last found that it depended on the way the scalpel was held in the fingers. If grasped by the end of its non-conducting ivory handle, there were no convulsions in the legs when the spark was taken from the machine; but if

[1] Aloysii Galvani de Viribus Electricitatis in motu musculari Commentarius. De Bononiensi Scientiarum et Artium Instituo atque Academia Commentarii, Tomus Septimus 1791, p. 363.

held in such a way that the fingers touched the steel blade, or the rivets which held it in place, the muscles were always thrown into action. The human body, therefore, served as a conductor, and Galvani replaced it with success by an iron wire which he attached by one extremity to the spinal column, above the origin of the nerves, by a brass or copper hook, leaving the other end in communication with the ground. He varied the contrivance in many ways, turning sometimes the attached and sometimes the free end of the conductor towards the electrical machine, increasing or diminishing its length, and at last adding a second conductor, attached to the muscles of the leg. He took special pains to exclude the possibility of any direct transfer of electricity from his machine to the dissected frog, and yet convinced himself, by the aid of Volta's electrometer, that in some way or other an electric discharge passed through the frog and was the exciting cause of its convulsions.

These experiments were all performed with artificial electricity, obtained from the electrical machine. Galvani then passed to his second series of observations, to see whether a similar effect would be produced by atmospheric electricity. On the approach of a thunder-storm he arranged one of the conducting wires so that its upper extremity was in the open air near the roof of his house, and its lower extremity connected with the frog's spinal column, while the other wire, attached to the muscles of the leg, communicated below with the water in a well, and he then waited, like Franklin, for the discharge of a thunder-cloud. The result followed as before; and every peal was accompanied by a convulsive motion in the dissected frog. He especially noticed that the convulsions were simultaneous not with the sound of the thunder, but with the electric discharges; for, as he says, "the muscular contractions and movements of the animal, like the visible splendor of the lightning flash, always preceded the thunder-clap, and, as it were, gave notice that it was coming."

So far Galvani had not really touched upon his final discovery. The phenomena of muscular contraction, in these two sets of experiments, were due, as we now know, to the action of induced electricity.

When he charged the prime conductor of his electrical machine, or when the thunder-cloud was passing over his house, an imperceptible but real disturbance of the electric equilibrium took place by induction in the wires attached to his dissected frog; and when the original electrical tension expended itself in a discharge, there was a similar reaction in his conducting wires, a reaction which necessarily passed through the nerves and muscles of the frog, and threw it into convulsion.

Galvani did not understand this; but he was engrossed with the idea of pursuing the new fact which he had unexpectedly witnessed, and of following its investigation by whatever path might be open to him. So it happened that he was led, in his third set of experiments, to a result of far greater importance, and, notwithstanding that the two former series had nothing to do with this result, so far as the nature of their phenomena were concerned, they were still the necessary and perfectly natural preliminaries to its discovery.

Galvani knew that the violent disturbances of thunder and lightning were not the only ones which take place in the atmosphere, but there were also other changes of electrical condition going on more quietly in ordinary weather. "After having tested," he says, "the action of atmospheric electricity in thunder-storm, I was exceedingly desirous of investigating it in its daily condition of quietude and serenity." For this purpose he hung his freshly dissected frogs, by copper hooks attached to the spinal column, from the iron railing of a balustrade about his house, and left them there exposed to the sky. He thought that, perhaps, imperceptible exchange of electricity between the clouds and the atmosphere might be betrayed by some movement in the frogs' limbs, and he watched patiently with that object for several days. But there was not the least indication of muscular excitement. At last, seeing that nothing further would come of the experiment in that way, he shifted the position of the limbs, and pressed them, still hanging by their hooks, against the iron framework of the balustrade, and instantly a convulsion took place. He had made a galvanic circuit. The copper hook and the iron railing were the two metals of the battery; and by bringing the muscles in contact with the railing, he had completed the communication, and had seen, for the first time, a muscular contraction excited by the galvanic current.

But, of course, his knowledge of the real cause of the contraction was still very incomplete, and no one could be more conscious of this than himself. He knew how many sources of error there may be in drawing a conclusion from visible facts, until they have been examined from every direction. His most natural inference, if he remained satisfied with this experiment, would have been, that the electrical cause of the contraction came from the atmosphere. "I was very much inclined," he says, "to attribute these contractions to atmospheric electricity, which had accumulated in the frog, and was then suddenly discharged by the contact of the hooks and railings, never having seen contractions produced in this way except in the open air, as I had not yet tried them in any other place; we may be so easily misled into thinking that we have really seen whatever we hope or expect to see." But he soon found that he could obtain the same results in his closed laboratory as in the open air, at any time of the day, in any weather, and under a great variety of conditions; provided only that communication was made between the nerves and muscles by metallic conductors, with no intervening non-conducting material. The best arrangement was that in which the nerves were suspended by copper hooks or armed with tin-foil, while the denuded feet of the frog rested on a silver plate, and the two were then connected by a metallic arc. The human body, being also a conductor, might be interposed between the ends of the arc without lessening the result. Galvani's description of this part of the discovery is an interesting episode, as it corroborates his proof of the electric nature of the force in operation. He found that if he held the frog suspended by its copper hook in one hand, and touched the silver plate with a metallic rod in the other, the frog was convulsed.

Then he called in the assistance of a colleague. "I was staying," he says, "at the country house of the most noble and excellent Signor James Zambeccari, where Signor Rialpo, of Spain, formerly a member of the Society of Jesus, and a very learned man, was visiting at the same time. He had already kindly aided me in former experiments, and I begged him to do so again in this instance. He accordingly took my place in holding the frog, while, partly for convenience, and partly to vary the conditions of the experiments, I, myself, touched the silver plate with my metallic rod. But, contrary to expectation, no movement was produced."

Then the two observers joined hands, and, on repeating the metallic contact, found, "to their delight," that communication took place through the human electric chain, and was manifested by muscular contraction in the frog's legs. From all these results, the conclusion became irresistible that the convulsions, previously observed in the frogs attached to the iron railings, were due to the contact of their metallic supports.

It is perfectly evident that this third set of experiments contains the substance of a new discovery, and Galvani fully recognized the fact. In the two former

series there were external sources of electricity, either in the electrical machine or in the thunder-clouds of the atmosphere; but here all such conditions were excluded—there was nothing to explain the phenomena but the frog's nerves and muscles and the metallic conductors between them. In all Galvani's experiments, his mind was forcibly impressed by this fact; and he was naturally led to suspect that the electricity which caused the convulsions might be derived from the animal body itself.

He made many attempts to determine which of the two kinds of electricity was produced in the nerves and which in the muscles, thinking one of these tissues would naturally be positive and the other negative; but he finally considered the electricity to be distributed on the exterior and in the interior of the muscles, very much as it is on the outer and inner surfaces of a Leyden-jar. The nerve, with its ramifications, leading from the interior of the muscles, he regarded as analogous to the chain and knob of the Leyden-jar; and when it was connected by a metallic arc with the exterior of the muscle, the animal electric battery was discharged, and a convulsion ensued from the stimulus of the shock.

In this way Galvani accounted for the phenomena witnessed in his experiments. He was far from believing that he fully understood all their relations, but he was convinced of their importance, and had no doubt that their obscurities would disappear on further investigation. He especially noticed the advantage of uniting in the armature of the limbs or in the connecting arc different metallic substances. "There is an additional peculiarity," he says, "which deserves attention, and which I have very often observed, in regard to the connecting arcs, namely, that they are vastly more efficient when composed of different metallic substances than when consisting of one and the same metal." But he does not undertake to explain this peculiarity, although he found that, of various metallic combinations, some were more effective than others.

He was perfectly clear as to the prime importance of what he had actually discovered and the secondary value of what was only inferential, and this distinction is expressly stated in his opening chapter. "From all these particulars," he says, "investigated and established by a long series of experiments, we have not only shown that these contractions are due to electricity, but have also been able to indicate certain conditions and laws by which they are regulated. . . . We have also appended to the narrative a number of corollaries, together with some additional conjectures and hypotheses, mainly in the hope of opening the way for further experiments, by which we may at least be enabled to approximate the truth, even if we cannot expect to reach it altogether."

There are some curious surmises in Galvani's book as to the possible future value of his discoveries in the treatment and cure of nervous disease. He recognizes the difficulty of their application to pathology, on his own hypothesis of an animal electricity as the cause of muscular contraction. But they are interesting in connection with the imperfect state of pathological knowledge in his day as compared with the present, and some of his remarks sound almost prophetic. "In regard," he says, "to the cure of paralysis, I see that it is a matter of great uncertainty. For it is not easy to say whether disease be caused by a degeneration of structure in the nerves and brain, or whether it be due to an obstruction of the supposed electrical circuits by the deposit of some non-conducting material."

"But, perhaps," he adds, "the whole thing will some day or other be cleared up by further practice and experience." Galvani did not have to wait long to see a very important advance made in the path which he had opened. One of his contemporaries was Volta, who had already been for fifteen years professor of physics in the University of Pavia, and who was admirably fitted, both by his capacity and his attainments, for treating a new subject with success.

Volta was greatly attracted by the novelty and character of Galvani's experiments. He repeated them, with many extensions and variations; and he not only verified their results, but was enabled to throw a new light on the immediate cause of their phenomena. His first investigations were communicated in the form of two letters to the Royal Society of London, in 1793, under the title "An Account of some Discoveries made by M. Galvani, with Experiments and Observations on them."[1]

In this communication he refers to Galvani's treatise, published two years before, as containing "one of the most splendid and striking discoveries, as well as the germ of others in addition."

Volta naturally approached the subject rather from its physical than its physiological side, and he had a certain mathematical habit of mind that led him to appreciate the value of quantities in such an investigation. He began by determining, in an approximate way, the amount of electrical stimulus capable of producing convulsions in the muscles of the frog.

By using successively smaller and smaller charges from a Leyden-jar, he found that the entire and living frog might be convulsed by electric discharges which would give but very faint sparks, and which would affect only the most delicate of the electrometers then in use. But a recently killed frog, prepared after the method of Galvani, was more sensitive still. In this condition it could be made to contract by an electric discharge fifty or sixty times more feeble, and quite imperceptible with any electrometer unless by aid of the condenser. In this way he exhibited Galvani's frog as a new kind of electrometer or electroscope, of extraordinary sensibility; and he named it accordingly the "animal electrometer." This showed conclusively that in all the experiments with induced electricity, the dissected frog might be convulsed by an electric discharge too feeble to be detected by other means.

Volta then began to investigate the source of electricity in Galvani's third set of experiments, namely, those with the dissected frog and the metallic arc. Galvani, it will be remembered, attributed this electricity to the different condition of the animal tissues, and always made his connection between the nerve on the one hand and the muscles on the other, as he would between the two surfaces of a Leyden-jar.

With the connection made in this way, the effect is really more striking, because the whole of the galvanic current passed through the insulated nerve, and thus produced a corresponding excitement. But Volta found that the two separate elements of nerve and muscle respectively were not essential to the result.

If one metallic armature were placed on the muscle and the other also on the muscle near by, or if they were placed on corresponding muscular parts of the two legs, a contraction ensued on connecting them by the metallic arc. The same thing happened with the nerve. If an armature of silver were placed on one part of the crural nerve above its junction with the muscles, and one of tin-foil at another part of the same nerve still higher up, and connection made between them, the leg was convulsed, notwithstanding that the whole of the muscles, as well as a portion of the nerve, were outside of the electric circuit. This did not correspond with the idea of an animal electric apparatus consisting of the nerve and muscles combined. It was necessary to look elsewhere for the source of the electricity under

[1] Philosophical Transactions of the Royal Society of London, for the year 1793, page 10.

these conditions, and Volta found it in the contact which developed but a minute quantity of electricity, too small to be recognized by any other means at the command of the experimenter; but the dissected frog was an electroscope of such sensibility that it responded to the test, and betrayed the electric discharge by a convulsion.

Volta was in very much the same position for this part of the discovery as Galvani had been in regard to his own earlier observations. He was compelled to recognize its reality and importance without being able to give its explanation. "I confess," he says, "it is not easy to understand how or why the application of dissimilar armatures, that is, of different metals, to two similar parts of the animal, or even to neighboring parts of the same muscle, should disturb the equilibrium of the electric fluid, and drive it from its condition of repose into one of active and continued displacement. But whatever may be the cause of the phenomenon, and whether intelligible or not, it is nevertheless a fact, abundantly established by the experiments already detailed, and further corroborated by those which follow."

For several years Volta continued the study of his subject, and at last found a way of greatly increasing the intensity of the phenomena, by multiplying the number of pairs of his dissimilar metals, so as to form the Voltaic pile. His results were given in 1800, in a letter to the Royal Society,[1] containing a description of his new contrivance.

Each member of the pile consisted of a plate of zinc in contact with a plate of silver. This was covered by a layer of moistened paper or membrane. Then followed a second pair of zinc and silver plates, and so on, alternately; the two metals always recurring in the same order, and each pair being separated from those above and below by moist membranes. With this arrangement the intensity of the action, on connecting the extremities of the pile, was sufficient to cause shocks and muscular contractions in the hands and arms, and to affect the senses of sight, hearing, taste, and touch. Its operation was compared to that of the torpedo and electrical eel, and it received the name of the "artificial electrical organ."

The peculiarity of this discovery was that it introduced into electrical science two new features. Before that time electricity had been obtained only by the combined use of different substances, one of which must be a conductor, the other a non-conductor, as in the frictional machine, the Leyden-jar, and the electrophorus; and when an electrified body was touched by a conductor, the whole of its charge was expended, and it could be electrified again only by receiving a new charge from an extraneous source. But in the electric pile Volta found, to his surprise, a source of electricity in substances all of which were conductors; and, furthermore, a source which seemed inexhaustible, because, however often the two ends of the pile were touched, the same shock was repeated with the same intensity. The inherent force of the pile seemed to urge the electric fluid incessantly forward, returning upon itself in a continuous flow so long as the circuit of conductors remained complete.

Volta attributed this action entirely to the contact of dissimilar metals. This view is plainly expressed in the title of his letter to the Royal Society, and is repeatedly insisted on in the course of the communication. The fluids are moistened membranes, interposed between the metallic pairs, which he regarded only as conductors; and when a saline solution was found to be more efficient than water alone, he thought it was because the salt increased the conducting power of the water.

[1] Philosophical Transactions of the Royal Society of London, for the year 1800, page 403.

In reality, the source of power in the Voltaic pile is the chemical action between the fluid and the metals, one of which is more oxidizable than the other; and for every unit of electric force sent through the circuit, a definite quantity of material undergoes chemical transformation.

The contact of dissimilar metals is not essential to the result, for a current may be produced without it, if we use two different liquids of which one is more decomposable than the other.[1]

Neither the first nor the second explanation of the phenomena observed, was, therefore, entirely right, as we understand it. Volta imagined the metals in his pile to act by contact alone, while they are really consumed by oxidation.

In Galvani's experiment, the connecting arc, where the two metals join, is, as Galvani supposed, a conductor and nothing more; but its different extremities, when applied to the animal tissues, form with them a galvanic battery of a single cell, and thus produce the current which excites their contraction. We now use it, for physiological purposes, in a different way. We place the two metallic plates in a cup of acidulated fluid, and make the returning current pass through the muscles and nerves. But the effect is the same, for the active force of the current is equal in both directions.

The results obtained by these two investigations were distinct from each other, but of almost equal importance. Galvani discovered the electric action on nerves and muscles which bears his name. Volta gave to physical science a new apparatus by which current electricity is transmitted in a continuous circuit. Each investigator was partially at fault in the theoretical explanation of his own discovery. But the value of the discovery has remained, and has even largely increased in the course of a century, notwithstanding the difference in its interpretation. It also appears, from the history of the circumstances, that the second of these discoveries was a consequence of the first; and nothing can show more clearly the unbroken connection of events, in the progress of science, which may sometimes extend to the most unexpected ramifications. It is plain that we should not be to-day in possession of the electric light, were it not for Volta's discovery of current electricity, and Volta produced his electric pile in trying to investigate the contraction of Galvani's frogs.

During the early part of the present century experimenters were busily occupied with galvanic electricity. They studied its action in a great variety of ways, and thus became acquainted with its mode of operation, and able to appreciate its phenomena. They found that when it was transmitted through any portion of a muscle, it produced contraction at the instant of closing the circuit; that afterward, while flowing through the nerve in a uniform current, it was without effect; and that contraction again occurred when the current was discontinued. Even during the passage of the current, any sudden variation in its intensity, either of increase or diminution, would produce the same effect. It was the change in the electrical state of the parts, rather than their actual condition, which operated as a stimulus and provoked the contractions. The direction of the current, the length of nerve included within the circuit, and the frequency of making and breaking the connection, all had a certain influence in the result. Experimenters found themselves provided with a new agent, by which they could investigate nervous action at their leisure, in animals deprived of life, with the nerves and muscles exposed to view, and with far more delicacy and certainty than ever before; and the

[1] Daniell, Introduction to the study of Chemical Philosophy, London, 1843, page 492.

familiarity thus acquired with the operation of the galvanic stimulus, prepared them for its more effective use in future investigations.

The next event of sufficient consequence to form an epoch in the history of nervous physiology was the discovery, in 1822, of the distinction of motor and sensitive properties in the two roots of the spinal nerves. Eleven years before, Charles Bell[1] had made some experiments on the spinal nerve roots of a recently killed rabbit, in which it appeared that mechanical irritation of the anterior roots caused convulsion in the corresponding muscle, while a similar irritation of the posterior roots had no such effect. This, however, was not supposed to show an anatomical separation between the two powers of motion and sensibility, but between those of volition and consciousness, on the one hand, and involuntary nervous action on the other. The ideas of the author on this subject were not accepted by his colleagues. In fact, they were not really published, but only printed in pamphlet form for private distribution. They hardly attracted the notice of the professors, and had no influence on the medical doctrines of the day. Subsequently, in 1821, Bell published[2] the remarkable observation that if the seventh cranial nerve distributed to the face were divided in a living animal, the movements of facial expression were abolished; while the faculty of sensation could be destroyed by cutting the corresponding branches of the fifth pair.

Thus the two main properties of nervous endowment, generally associated with each other, occupied, in this instance, distinct situations; since the seventh was shown to be a nerve of motion only, the sensibility of the face being supplied from another source. This fact was connected, in the researches of Sir Charles Bell, with theoretical considerations of a different bearing; but it had evidently a great importance of its own, and was received on all sides with much interest. It especially attracted the attention of Magendie, then at the height of his activity in physiological investigation. Magendie repeated Bell's experiments on the seventh cranial nerve, and verified their results as to its exclusively motor properties. But he was intent on exploring various other parts of the nervous system; and in 1822 he performed and published his experiments on the spinal nerve roots. His description is a model of directness and simplicity, free from any unwarranted inference or assumption. "I had long been wishing," he says, "to try the experiment of dividing the posterior roots of the spinal nerves, but had never succeeded in doing so, owing to the difficulty of opening the vertebral canal without wounding the spinal cord and inflicting severe or fatal injury upon the animal. But a month ago I received at the laboratory a litter of pups, only six weeks old, and it seemed a good opportunity for another attempt at the operation. This time, in fact, I succeeded, by the aid of a very sharp scalpel, in laying bare, almost at a single stroke, the posterior half of the spinal cord with its membranes. I then had no difficulty, after opening the dura mater, in bringing into view the posterior roots of the lumbar and sacral nerves; and by lifting these roots on the blades of a pair of fine scissors, I was able to divide them on one side without injury to the spinal cord. Not knowing what would be the effect of this operation, I closed the wound by a suture in the integument and kept watch of the animal. At first it looked as if the limb on that side was entirely paralyzed. It was insensible to punctures and to pressure, and also appeared motionless; but soon afterwards I was surprised by seeing it move very distinctly, although it was completely and permanently insensible. After trying a second and a third experiment, with exactly the same result, I began to think it probable that the posterior roots of the spinal nerves might have a function distinct from that of the anterior roots, and more especially devoted to sensibility.

"I next thought of dividing the anterior roots, leaving the posterior roots entire; but that was a thing more easily said than done. There appeared to be no way of getting at the anterior surface of the cord without involving the posterior roots, and at first it seemed a hopeless undertaking. After considering the matter for a day or two, I tried to reach the anterior roots with a sort of narrow-bladed cataract-knife, by passing it in front of the posterior roots, and then turning its cutting edge against the bodies of the vertebræ. This plan failed, owing to unavoidable hæmorrhage from the large veins within the vertebral canal; but while making the attempt, I found that by drawing aside the dura mater, I could catch a glimpse of the anterior roots just where they are about to pass through the investing-sheath. This was enough; and in a few seconds more I had divided as many of them as I wished, on one side only. It may be imagined with what curiosity I awaited the result. It finally came in a perfectly unequivocal form; for the limb, though retaining its sensibility, was completely relaxed and motionless. Finally, not to leave anything undone, I divided both the anterior and posterior roots, causing entire loss of sensibility and motion."

Magendie began his experiments, therefore, by dividing the nerve roots and thus abolishing their functions. In pursuing the subject he tried the effect of their irritation, employing for this purpose both mechanical agents and the stimulus of galvanism. The result of these experiments correspond in general with those obtained by the method of division; that is, galvanization of the anterior roots caused muscular contraction, and that of the posterior roots sensation. There were also certain other phenomena which did not altogether coincide with the doctrine of a complete separation between the two functions, and which were not fully understood until some years later. But Magendie took cognizance of every experimental fact, whether he understood it or not; and his own subsequent researches on "recurrent sensibility" explained many of the irregularities which he at first encountered.

The distinction of properties between the spinal nerve roots was of great importance, because it indicated a general plan of arrangement for the nervous system throughout the body. It immediately became a matter of criticism and verification for the leading physiologists of Europe, and the result was a complete acceptance of Magendie's discovery.

In Germany, John Müller, then Professor of Anatomy and Physiology in the University of Bonn, endeavored to avoid the difficulties of so serious an operation in warm-blooded animals by experimenting on frogs. He examined the spinal nerve roots in these animals, both by the method of section, by mechanical irritation, and by galvanism.[1]

"These experiments," he says, "have been rewarded with the most brilliant success. They are so easy of application, so sure and so decisive, that any investigator may now readily satisfy himself of one of the most important truths in physiology. The phenomena are so regular and satisfactory that, for simplicity and certainty of results, they fully compare with any crucial experiment in the physical sciences. Galvanization of the separated anterior roots at once causes active con-

[1] Idea of a new Anatomy of the Brain; submitted for the observation of his friends, by Charles Bell, F.R.S.E.

[1] Handbuch der Physiologie des Menschen, Coblenz, 1837. Band I., page 651.

vulsions; that of the posterior roots never gives rise to any sign of spasmodic action."

In this way the distinct endowment of the two kinds of nerve-fibres was experimentally established. Once placed on this footing, pursuit of nervous physiology was greatly increased in efficiency and extent. By applying the galvanic stimulus to a spinal nerve above or below the point of section, its mode of action was determined by the excitability of its motor or sensitive fibres. The same method was employed for the cranial nerves, both externally and at their roots; and every branch of inosculation was scrutinized by the same means. It is hardly possible to overestimate the change thus introduced into the study of the nervous system, and the increased facilities which it supplied for further investigation.

We now come to Marshall Hall's discovery of the reflex action of the spinal cord. Up to this time, the motor and sensitive properties of the nervous system had been understood by physiologists as almost wholly subservient to voluntary motion and conscious sensation. These functions resided in the brain as the organ of intelligence and the source of all spontaneous action. From it the motor nerves transmitted to the muscles the commands of the will, while the sensitive nerves brought to it from without the impressions made on the integument. The spinal cord was part of this apparatus of transmission. Like the spinal nerve roots under the influence of galvanism, its posterior columns were found to be sensitive and its anterior columns excitable, and its complete division at any one point abolished voluntary movements and sensation in the parts below. It was the channel through which the spinal nerves held their connection with the brain.

But Hall observed that, notwithstanding the loss of sensation and volition after removal of the brain, the animal might still be capable of motion in the limbs, provided the spinal cord remained.

Although phenomena of this kind had already been noticed in several instances, they had not been demonstrated with sufficient distinctness to fix the attention of physiologists. Hall's observations were first announced in a communication to the London Zoological Society in 1832. They were further embodied in his *Lectures on the Nervous System and its Diseases*, in 1836, and still more formally presented in his *Memoirs on the Nervous System*, in 1837. Their simplest demonstration was given by him in the following way: In a living and uninjured frog, the signs of sensation and volition are manifested whenever the skin is irritated at any point, since the animal feels the impression and responds to it by a voluntary motion. When the head is cut off, or the spinal cord divided at its upper part, the limbs are paralyzed and sensation is abolished. But if, while the animal is in this condition, one of the feet be pinched, the limb is drawn upward; and the movement may be repeated as often as the irritation is applied. Such a movement is very different from that caused by galvanizing a motor nerve, since the stimulus in this instance is applied to the skin, and the muscles react in consequence. Both skin and muscles must retain their connection with the spinal cord; since, if this connection be cut off, no movement takes place on pinching the foot. Finally, the nerves remaining uninjured, if the spinal cord be broken up, all reaction ceases, and irritation of the skin has no further effect. But does not such a violence destroy the physiological property of the muscles, and in that way prevent their contraction? This doubt is removed by applying a galvanic current to the muscles themselves, when they are at once convulsed, showing that their contractile power is unimpaired.[1]

[1] Lectures on the Nervous System and its Diseases. London, 1836, p. 19.

Thus it is the spinal cord, which acts independently of the brain, is a medium of communication between the integument and the muscles. The stimulus conveyed inward, through the sensitive nerves to the cord, is thence reflected outward through the motor nerves to the muscles. From this circumstance it received its name of "reflex action," and, since it was first studied and demonstrated in the spinal cord, it was generally known as the "reflex action of the spinal cord."

But the same form of activity was afterwards found to be very widely extended in the nervous system. The medulla oblongata has its own centres of reflex action, either directly or indirectly essential to the continuance of life. Wherever there is a ganglionic mass of nervous matter, with motor and sensitive fibres originating from it, there is a similar focus of nervous power, often quite disconnected with consciousness and volition. In a state of absolute insensibility, in a man or animal, a touch upon the cornea will cause closure of the eyelids, irritation of the anus will increase the contraction of the sphincter, and the contact of a solid body with the fauces will excite the movement of deglutition; and in all these instances the reaction disappears when its special nervous centre is destroyed.

Similar facts were soon observed in man in cases of paralysis, and nearly all of the phenomena of convulsive affections were seen to have their origin in some unusual irritation of a nervous centre, or in the morbid exaggeration of its excitability. From that time forward the reflex action of the nervous system entered more or less into the whole study of its normal and diseased conditions.

The next topic of special interest in this connection is the influence of the nervous system on the organs of circulation. The earlier approach to definite knowledge on this subject was a very slow one. It consisted mainly in establishing the fact of contractility in the arteries, and was accomplished by experimental enquiries extending over a long time; from those of Hunter on the arteries of animals in 1793, to those of Kölliker[1] in 1849, on the constriction caused by galvanism in the popliteal and tibial arteries of an amputated human limb. A new epoch in the physiology of the circulation was reached in 1851, when Claude Bernard[2] published the discovery that division of the sympathetic nerve in the neck is followed by enlargement of the head. This effect is so striking and so constant, that when once announced, there was no difficulty in its verification and no doubt as to its reality. Almost immediately after section of the nerve, an increased vascularity becomes visible in the conjunctiva, the mucous membrane of the nostril, lip, tongue, and cheek, and in all parts of the skin on the affected side. It is most distinctly seen in the ear of the white rabbit, because the organ presents a thin expansion of semi-transparent tissue convenient for observation, and because the two ears placed side by side afford a ready criterion of any change in vascularity. In the first report of these experiments the attention of the observer was principally directed to the local increase of temperature which also follows division of the sympathetic, but this was afterward seen to depend on the greater activity of the circulation, which was then recognized as the primary and characteristic result of the operation.

This fact of enlargement of the bloodvessels from division of the sympathetic nerve, at once excited a lively interest among physiologists. Hardly a year had elapsed, when a second observation, equally important

[1] Zeitschrift für Wissenschaftliche Zoologie, Leipzig, 1849, Band I., p. 259.

[2] Comptes Rendus de la Société de Biologie, Paris, Tome Année 1851, p. 163.

with the first, was made almost simultaneously by Brown-Séquard, in Philadelphia,[1] Bernard, in Paris,[2] and Waller, in London;[3] namely, that the condition of the circulation, on that side of the head where the sympathetic has been divided, may be regulated at will by experimental means. Suppose that increased vascularity has been produced by division of the sympathetic in the neck. If the stimulus of galvanism be now applied to the divided nerve beyond its point of section, all the previous results of the operation disappear. The bloodvessels contract, the volume of the circulation diminishes, the local temperature is reduced, and the parts resume their normal color, or even become more pallid than before. When the galvanization is suspended, the former conditions return with all the accompanying phenomena of vascularity, temperature, and redness; and the circulation in the part may be in this way alternately increased and diminished for many successive repetitions of the experiment.

It thus appears that the muscular coat of the arteries, supplied with nerve fibres from the sympathetic, is influenced by them in nearly the same way as the voluntary muscles are controlled by the cerebro-spinal nerves. Division of the sympathetic paralyzes the involuntary muscular fibres, relaxes the arterial walls, and allows a larger quantity of blood to pass through the vessels of the part. Galvanization of the nerve, on the other hand, stimulates the muscular fibres to contraction, narrows the calibre of the vessels, and so reduces the volume of the circulating blood. The knowledge of these facts introduced into the nomenclature of the nervous system a new title. There were evidently nerve fibres which acted upon the bloodvessels to call into operation their contractile power; and the nerves possessing such a function, then known for the first time, naturally received the name of the "vaso-motor nerves."

But, in following out this subject, another observation was soon met with, of very different and unexpected character, namely, that certain nerves, on being stimulated, instead of producing contraction of the bloodvessels, cause their relaxation and thus increase the activity of the circulation. This was first shown by Bernard in the case of the submaxillary gland. This organ is supplied with sympathetic fibres from the superior cervical ganglion and carotid plexus, and with cerebro-spinal fibres from the lingual nerve and the chorda tympani. Galvanization of its sympathetic filaments produces, as in other similar instances, contraction of the bloodvessels and a diminished blood supply. But if the stimulus be applied to the lingual nerve above the situation of the gland, or to the chorda tympani which unites with it, the result is exactly the contrary. The bloodvessels enlarge and the circulation is more active so long as the galvanization continues; and this effect is equally marked if the nerve be divided and galvanized between its point of section and the gland.

A similar influence was found to reside in other parts of the nervous system; and the nerves possessing the power of thus causing vascular enlargement were called "dilator nerves." No sooner was this fact established in a general way, than it served to explain a singular phenomenon which had been noticed many years before, but which had thus far been regarded as exceptional, namely, the influence of the pneumogastric nerve on the action of the heart. As a general rule, if the nerve going to a muscular organ be divided, the muscle is paralyzed, and, if the nerve be stimulated, there is a muscular contraction. As the heart receives filaments from the pneumogastric nerve, we should naturally expect that its action would be diminished by section of this nerve, and increased by its stimulation. But the effect is really the reverse. If the poles of a galvanic apparatus be applied to the pneumogastric nerve in the neck the cardiac pulsations are reduced in frequency, and when the strength of the current is increased to a certain degree they stop altogether. The heart lies quiescent, in a state of relaxation, its movements remaining in abeyance while the galvanization is going on, and when it is suspended they recommence with undiminished energy. The influence exerted in this case is not reflex, but direct in its operation. For if the nerve be divided and galvanized above its point of section, there is no result; but if the stimulus be applied below the section, its retarding action on the heart is at once manifested. Furthermore, the power of this nerve to restrain the cardiac movements, like the motor influence of a spinal nerve, is limited in duration. You cannot permanently arrest the heart, and so kill the animal, by continued galvanization of the pneumogastric. When the galvanization of the nerve has been kept up for a certain time the heart begins to beat again. Its pulsations recur, at first, slowly, afterwards, more frequently, and at last they are restored in full regularity, notwithstanding the continuance of the galvanic current. The nerve has lost its power by expansion, and cannot again manifest its controlling force unless allowed to recover by repose. But the heart is still sensitive to the same influence, and if the electrodes be shifted to the pneumogastric of the opposite side it stops as quickly as before.

It must be admitted, therefore, that the influence of the pneumogastric, whatever it may be, which controls the heart's movements, is transmitted from within outward to the peripheral extremities of the nerve; and that it acts in a positive way. It is the most striking illustration of a kind of action in the nervous system, unlike any of those formerly known, but not the less real for being difficult to understand. This is the so-called "action of arrest;" an influence which passes through a nerve from its nervous centre to a muscle, and by which the muscular contraction is suspended. As often happens in such cases, when the existence of this mode of action was once realized, it appeared that there were other instances of the same thing, which had been overlooked. All the sphincter muscles, though habitually in a state of involuntry contraction, are suddenly relaxed at certain periods, by an influence coming from within. The bloodvessels generally received both kinds of nervous impression, and by the varying preponderance of one or the other, they are alternately made to contract or dilate, with all the accompanying changes of local circulation. In this way it became possible to explain the mechanism of temporary physiological congestion, as in secreting glands, or in the alimentary canal during digestion, and those of longer continuance with increased nutrition, like the growth of the uterus and mammary glands during pregnancy, as well as morbid disturbances of the circulation in disease.

Quite a different line of investigation was inaugurated by Helmholtz, in 1851, for determining the rapidity with which nervous action is transmitted through the motor nerves.[1] The idea of measuring, with any approach to numerical precision, the movement of the intangible nerve-force, through its fibres, would seem at first almost beyond the scope of reality; and yet it was accomplished with satisfactory success and by perfectly genuine experimental methods. It would have been impossible were it not for improvements in the galvanic apparatus and the registering machines, which have

played so important a part in the more recent investigation of animal physics. The knowledge and use of the induced electric currents we owe to Faraday; and their discovery in 1831, with all the related phenomena of electro-magnetism, magneto-electricity, and the production of instantaneous and rapidly alternating opposite currents, practically revolutionized the use of electricity for medical purposes. It also supplied essential facilities for experiments on the rate of transmission of the nerve-force.

The conditions necessary for such an experiment were twofold. First, an instantaneous induced current, for causing a single muscular spasm; and secondly, an automatic registering apparatus, which should mark the exact time, both of the electric stimulus and of the muscular action. By this means a definite result was obtained. With the electrodes applied to the muscles of a frog's leg, an interval, amounting to the one-hundredth part of a second, appeared between the closure of the circuit and the contraction of the muscle. The muscular contraction, therefore, was not an instantaneous effect, but required a certain time to get under way after the application of the stimulus. This interval was not perceptibly altered on applying the electrodes to the nerve at or near its entrance into the muscular tissue. But if they were applied higher up on the nervous trunk, the delay became longer; and it was increased in subsequent trials, exactly in proportion to the distance between the muscle and the point of the nerve stimulation. It represented, accordingly, the time required for the nerve-force to traverse a given length of nerve fibre; and by repeating the test under various conditions, its rate of movement was fairly determined.

These experiments, first performed on the nerves and muscles of the separated frog's leg, were afterwards extended to those of the living man—the electric stimulus being applied to the skin over the situation of a nerve at different points, and the connection indicated by the swelling of the parts over the muscle. In all the investigations thus far, the nerve was excited by the artificial stimulus of electricity.

Subsequently, Burckhardt[1] simplified the experiment and increased the value of its results by employing, instead of electricity, the natural stimulus of volition. The subject being placed in connection with a proper registering apparatus, the signal for voluntary effort was given by the sound of a bell; and the movement was performed in different instances by different muscles. Under these conditions, the time necessary both for volition and for the mechanism of muscular contraction, would be the same in all cases; but that required for traversing the motor nerve would vary according to the muscle employed. A voluntary impulse, starting from the brain, would arrive at the deltoid muscle after travelling a certain distance, but it would follow a longer route to reach the adductor of the thumb. The distribution of the crural nerve to the quadriceps extensor muscle is comparatively remote from its origin, and that of the sciatic nerve to the dorsal muscles of the foot more distant still.

The difference in the time of muscular contraction, observed in these cases, corresponded with the different lengths of nerve conveying the stimulus; and it gave, for the passage of the voluntary impulse, in man, through the motor nerves, an average rate of twenty-seven metres per second.

A similar contrivance for measuring the transmission of tactile impressions through the sensitive nerves, gave their rate of movement as forty-seven metres per second, showing a greater rapidity of transmission for sensitive impressions than for motor impulses, and by comparing the results of further experiments with the known quantities obtained in this way, a close estimate was reached of the time needed for the operation of the different senses, and even for the cerebral acts of perception and will.

When these observations were made on different persons, there was always a certain amount of variation in the result, the nervous action being in some cases more rapid, in others comparatively slow. This brought within the range of definite physiological experiment a fact first noticed in astronomical observatories, namely, that two observers, both watching for the same event, seldom see and record it at the same time. There is a difference in the quickness with which they receive its impression on the senses, and in each case there is a certain amount of delay, so that in neither the one nor the other is the phenomenon perceived at the time of its actual occurrence. In astronomical operations where extreme accuracy is required, as in transit observations for the determination of longitude, this personal imperfection of the observer needs to be corrected from a previous examination of his habitual error. In the Report of the United States Geographical Surveys for 1877, it is stated by Dr. Kampf that the personal error from this source varies somewhat, in the same individual, from day to day; so that its amount should be ascertained and the proper correction made, for each person, whenever a longitude observation is about to be taken.

There is still another point to be noticed in connection with the modern study of the nervous system, namely, the localization of function in different regions of the brain.

The most striking part of this subject relates to the special centres for motion and sensation in the cerebral convolutions. There are few discoveries which have seemed more at variance with our former convictions than that of the existence of these centres. Both the substance and the surface of the cerebrum had often been subjected to experimental examination, both in the living and the recently killed animal, without showing any signs of muscular reaction; and it was the universal belief among physiologists that none of its parts were directly subservient to any form of motion or sensibility. So industrious and skilful an observer as Longet[1] declared in 1869 that he had "irritated by mechanical means the white substance of the hemispheres in dogs, cats, rabbits, and birds, and had stimulated it by the application of potassa, nitric acid, or the actual cautery, as well as by the passage of electric currents in various directions, without ever bringing into play the involuntary muscular contractility or convulsive movements, and similar applications to the gray substance of the convolutions were equally without effect."

From these failures it seemed hopeless to anticipate any further results from direct exploration of the cerebral substance. The brain was generally considered as so exclusively the organ of intelligence, that it could not be expected to respond to the stimulus of physical agencies. In the extremely condensed and valuable work of Ecker on the *Convolutions of the Brain*, the author says in his preface, that "the accurate observation of patients by their physicians, in connection with careful autopsies, is the only means by which we can ever hope to learn the physiological significance of particular cerebral convolutions." This preface was dated March, 1869; and in 1870, Fritsch and Hitzig[2] discovered, by experiments with galvanism

[1] Die Physiologische Diagnostik der Nervenkrankheiten. Leipzig, 1875, p. 32.

[1] Traité de Physiologie, 3me Edition. Paris, 1869, Tome III., p. 146.

[2] Archive für Anatomie, Physiologie, und Wissenschaftliche Medicin, Leipzig, 1870, p. 300.

on the dog's brain, that there are certain parts of the cerebral convolutions where this stimulus always produces definite and unmistakable movements on the opposite side of the body. The contraction of certain groups of muscles, and consequently particular movements in the trunk or limbs, are connected with the stimulation of particular points of the brain; and where such a point is once found, the corresponding movement may be produced at will by repeating the application of the stimulus. There is plainly, in some way or other, a communication through definite nervous routes from the special centre of motion on the surface of the hemisphere to the motor tract in the medulla and spinal cord, and thence to the muscle which performs the contraction.

In all the animals used for experiment, these special centres are grouped in certain regions, while other extensive portions of the cerebral surface show no such indications; and by comparing their position in different species, aided by observations in human pathology, it appears that in man the motor centres for the body and limbs of the opposite side are mainly located in the anterior and posterior central convolutions, immediately bordering on the fissure of Rolando.

Thus the earlier failures and the more recent success in the discovery of the motor centres are both explained. It is true that a large part of the cerebral surface is inexcitable. You may apply the galvanic electrodes to twenty different points of the convolutions without the least sign of a muscular contraction; but on the twenty-first trial you may strike one of these centres, and then the muscular spasm immediately follows. We are now so well acquainted with their probable location in any particular brain, that we need not lose a great deal of time in finding one of them; but, before the geography of their distribution was known, it is not surprising that experimenters should have overlooked their existence.

The account given by Fritsch and Hitzig of their discoveries was exceedingly well expressed, and bore internal evidence of its faithfulness of description. All the phenomena were fully explained, and the results were stated in such a way that other observers could easily follow in the same direction and test their reality. Some doubt was entertained in various quarters as to the interpretation of the phenomena, and particularly how far the muscular contractions might be due to a diffusion of the galvanic current beyond the limits of its immediate locality; but this doubt was removed after repeating the experiments by a variety of methods, and the existence of the motor centres was corroborated by subsequent discoveries in the minute anatomy of the parts and by observations on the local alteration of structure in cases of hemiplegia. The subject is still so new, and in so active a condition of development, that it can hardly be presented in the form of a complete or well-defined physiological doctrine; but it is evidently a matter of great importance, and is probably receiving, at this time, a larger share of attention than any other single topic relating to the nervous system.

Its latest extension is connected with the centres of *sensation* in the cerebral hemispheres. As some parts of the convoluted surface of the brain are plainly subservient to muscular action, it is natural to infer that the remaining inexcitable portions may have a similar connection with the power of sensibility; and it is asserted by some, with more or less confidence, that the senses of touch, taste, smell, sight, and hearing are separately located in as many different regions of the cerebral cortex. The experimental evidence of these localizations is far from being altogether satisfactory; but in one instance at least it is very striking, and indicates beyond doubt a close relation of visual sensibility with the "angular convolution," on the posterior and lateral part of the cerebral hemisphere. If this convolution be extirpated, the operation is followed by blindness of the opposite eye, without any other perceptible disturbance of either motion or sensibility. As other parts of the same brain surface, of equal or greater extent, may be removed without causing impairment of vision, it is difficult to avoid the conclusion that this region has a special connection with the sense of sight. The exact nature of the connection will doubtless be better understood from further investigation.

The complete history of physiological science for the last hundred years, in regard to the nervous system, can hardly be given in the space of a single lecture. But its most important advances are so connected with each other, that they have a relation very much like that of cause and effect. When a new subject of inquiry is first opened, the progress made is for some time a slow one. There are difficulties in the way, which must be overcome by repeated experiments, by gradual improvement in the apparatus, and by better methods of procedure. The causes of the phenomena are imperfectly understood, and their relation with other observed facts is not immediately apparent. But when the knowledge acquired has reached a certain point, its evidence becomes more rapid. Every addition enlarges the circle of its operations, and enables it to execute them with greater facility, and the results attained by this means are not always those most directly anticipated. One discovery often leads to another by bringing into view incidental facts, which in turn become the sources of new information; and in that way it creates opportunities for future progress, which are sometimes realized in their fullest extent only aften an interval of several generations.

There is no more interesting department of physiological study, at the present day, than that of the vasomotor nervous system. Since it was first practically inaugurated by Bernard, thirty years ago, it has been cultivated by many observers, and has received a wide extension in many directions. It touches on most important points of pathology, as well as the functions of health. The connection between secretion and blood-supply, the mechanism of congestions, the dependence of external disturbances of the circulation on disease of internal parts, the red cheeks of pneumonia, the hectic of pulmonary phthisis, and the existance of nervous centres in the cerebro-spinal system, where these changes are controlled by reflex action, are all made capable of investigation by knowledge which has been derived from this source. But how could their study have been ever attempted unless we were already in possession of the simpler facts of reflex action of the spinal cord, and the different behavior of motor and sensitive nerve fibres? All the variations in the effect produced by electric stimulus of different kinds and intensity, the comparative influence of direct and inverse currents, the exhaustion of nerves by continued stimulation, and their recovery by repose, together with many other similar conditions, were indispensable stages in the progress of discovery, and were the fruit of many intermediate investigations. But each series depended, for the possibility of its existence, on another which had gone before, and they all had their origin, in a continuous line of descent, from the experiments of 1789 in Galvani's laboratory at Bologna.

ORIGINAL ARTICLES.

THE ABORTIVE TREATMENT OF FELON WITH COPAL VARNISH.

BY A. B. ISHAM, M. D.,
OF CINCINNATI, O.

FELON, or whitlow, has brought into practice devices intended to be curative, both professional and

domestic, nearly as numerous as bronchial catarrh. The maxim seems to find application here, that where a great number of agents are vaunted as specifics in a single affection, none have much value. At least, in my experience, the results of the various so-called abortive measures of treatment in felon have been very unsatisfactory. In fact, so utterly worthless had they proved, that I was about to settle down into the old routine method of poulticing and incisions, when one day, about a year ago, I met by chance a burly colored brother in a drug store; one of his hands was enveloped in flannel bandages of enormous dimensions, while his countenance and his groans betokened an intense degree of physical suffering. He volunteered the information that a regular physician to whom he had applied had pronounced him the subject of a deep-seated felon of the palm of the hand, and had proposed an incision through the inflamed tissues. Before submitting to incision, however, he intended to test the virtues of a prescription recommended by a sage of his own race, one who made plane surfaces, or the souls of sinners white, as exigencies demanded. The remedial agent advised was copal varnish. Flannel bandages were to be saturated with this, the affected part enwrapped therein, and dry flannel envelopes externally were to complete the dressing.

Three days thereafter I again saw the same individual carrying a hod. He wore a triumphant expression, and the previously bandaged member was bare, and, to all appearances, normal. He said that within a few hours after the application of the varnish, the pain ceased, and the swelling and heat were rapidly reduced. I made mention of the case to the physician who was reported to have been consulted. He stated that when he saw the hand there was a severe phlegmonous inflammation, that the member was swollen to apparently twice its natural size, and that, in all respects it resembled whitlow of the palm in the acute stage.

Notwithstanding the rather remarkable resolution in this instance, my anticipations from the employment of copal varnish in prospective cases of felon were by no means sanguine. The cogent influences leading to a trial of it, were that it was simple and harmless, and that it would serve to satisfy patients that something was being done for them fully as well as anything else, while it could not be inferior to any plan of treatment in vogue, short of free incision.

Since the observation above detailed, thirteen (13) cases of whitlow have presented to me for treatment. In six of these cases a formation of pus having already occurred, they were not deemed fit for the trial of the varnish, and incision was resorted to. In the other seven cases the varnish was the only agent used. The terminal phalanx of the thumb was the part involved in two; that of the index-finger in five cases. In all there was swelling, redness, heat, and great pain; in one a vivid erysipelatous blush extended over the thumb, wrist, and extensor surface of the forearm; in two cases there was apparently a combination of what is popularly called "run-around," with felon of the flexor digital surface, about and near the point. Perhaps in none was the periosteum involved, though several did not differ from cases I have seen in the acute stage, where necrosis and extrusion of the terminal phalanx subsequently took place. In all the seven cases to which the varnish was applied, there was a rapid subsidence of the inflammatory process and its accompaniments, and by the second or third day, the parts were perfectly normal.

If the varnish upon the dressings become unpleasantly hard by drying, it may be softened by adding fresh material from time to time. Its removal may be easily accomplished when found desirable, by rubbing in lard, and then washing with soap and water. Upon the basis of the good results of this limited experience, I shall yet continue to treat felon, and local acute inflammations of external parts, previous to the formation of pus, with copal varnish. No good could be expected of it, except possibly to relieve pain, after suppuration had ensued, since it is a cardinal axiom in surgery that, where pus is formed, it must have exit.

The rationale of the action of the varnish in such cases demands a consideration of the nature of inflammation, and the composition and properties of copal varnish.

According to the most authoritative observations, the initial process in inflammation consists in a dilatation of the peripheral vessels of the tissues compromised. Previous to this dilatation of capillary vessels, some influence has been transmitted to nervous centres impressive to vital conditions of particular structures, and from these centres the dilating impulse has been reflected through vaso-motor nerves. With dilatation, there is increase in the quantity and rapidity of the blood flow. Soon, however, the arterioles leading to the turgid capillaries undergo a contraction of their calibre. Then the capillary blood current is slowed, and the white globules arrange themselves against the vessel walls. There is a migration of these bodies through the walls, the liquor sanguinis transudes into the tissues, and the red blood disks aggregate in rouleaux in the vessels. Completing the process is an active cell proliferation in the inundated tissues.

Copal varnish is composed principally of copal resin and spirits of turpentine. Turpentine, according to the best information I can obtain, constitutes about three-fourths of the mixture, and to it, chiefly, we would attribute the beneficial action the varnish seems to possess in resolving whitlow. The use of turpentine in the treatment of localized inflammation is by no means new. As a topical application, it has been highly extolled in traumatic erysipelas, in boils and carbuncles, peritonitis, hepatitis, pleuritis, and pneumonitis. Its irritant properties hardly need mention. It is well known that it is rapidly absorbed into the system when brought into contact with the skin. That it has a great affinity for oxygen is also familiar. An instance is reported where a lad was found in an asphyxiated state in a cellar where turpentine was stored, and an examination of the cellar air showed that it had been nearly deprived of its oxygen. As the turpentine is separated from the varnish by absorption and evaporation, the resin contracts and hardens. Three ways are therefore

conceivable whereby copal varnish may promote resolution of local inflammation:

1. *By an irritant action.*—Experiments conducted under the microscope upon the inflamed web or mesentery of the frog, have shown that stasis has been overcome, and a flow established in blocked capillaries subjected to the irritation of dilute caustic soda solution, dilute sulphuric acid, ammonia, croton oil, etc. The ingredient of copal varnish which produces irritation is turpentine. A current restored in such manner, and operated upon by other forces, to be presently noticed, may continue, thereby stopping transudation and the migration of leucocytes. The changed conditions of circulation and pressure, resulting from the inflow of fresh blood, facilitate drainage from the surcharged tissues, reduce the bulk of the inflamed part, and materially conduce to a restoration to the normal state.

2. *By withdrawing oxygen and arresting oxidation.*—The attraction which turpentine manifests for oxygen has already been mentioned. By appropriating oxygen in the tissues, which it readily penetrates, it may modify oxidation processes, check cell proliferation, and liquefy inflammatory products so that they can be taken up by the absorbents, and be carried away for elimination. The power of turpentine to absorb oxygen also suggests that, in yet another way, this may not be by any means the least important of its capabilities. It has been shown that certain parasitic microphytes are present in furuncle and abscess, the origin and course of which are attributed to some special activity of such organisms. The researches of Dumas has established that these microphytes can be destroyed by boracic acid, which deprives them of oxygen. Dr. Loewenberg has recently made practical application of boracic acid in furunculosis, with an arrest of development in one instance from local application. Micrococci are found in the abscesses of felon as well as in those following other inflammations, and they are entitled to the same consideration as respects causation. Their vitality is destroyed by turpentine, by boracic acid, and some other agents, by withdrawing their oxygen. And turpentine has a superiority over other substances of this class as a local application, since it more readily penetrates the tissues, and exerts a wider and stronger action.

3. *By excluding air and by pressure.*—The idea that the atmospheric air, in contact with inflamed surfaces, exercises a deleterious influence, is as old as medicine. The varnish forms a coating impermeable to air, and therefore entirely excludes, from this source, any agency operating to favor inflammatory action. The varnish in drying contracts and exercises pressure. The value of pressure, in modifying and subduing inflammation, is familiar to all. Bandaging and strapping inflamed members are modes of applying pressure of the most common practice. Pressure moderates the supply of blood delivered to the part, while, at the same time, it promotes the removal of waste matters and tends to maintain a steady and continuous stream.

The above conclusions go to indicate that any varnish into which turpentine enters largely would serve as well as the copal. While the turpentine itself is doubtless the most important factor in the resolution, alone employed, it might be inefficient, since the resin, by forming a coating and by the pressure it exercises, may supply essential elements, and without which combination the former might be of slight advantage.

SYMPATHIES OF THE PAROTID GLAND.

BY R. B. MOWRY, M.D.,
OF ALLEGHENY, PENNA.

A GREAT deal of interest has been lately manifested in affections of the parotid gland, which induces me to report some cases which came under my observation.

John G., a boy of ten years, was attacked with typhlitis. I need not detail the symptoms; will only say it was a well-marked case of inflammation of the cæcum. After a few days' treatment, the symptoms of inflammation in that region seemed to disappear, and the left parotid gland swelled and went on to suppuration.

When the gland grew better, symptoms of inflammation again appeared in the region of the cæcum; these symptoms again suddenly subsided, and the right parotid inflamed and suppurated. When this parotid became better, symptoms of inflammation again appeared in the region of the cæcum. An abscess was finally formed, which discharged healthy pus, and the boy got well, with evident adhesion of the intestine to the parietes of the abdomen. This boy lived for some years in pretty good health, when from violent exercise—playing base-ball—a rupture was produced, an artificial anus formed, from the effects of which he finally died.

In this case there was no evidence of the formation of pus in the region of the cæcum, until after both parotids had recovered; nor were there at any time symptoms of blood-poisoning.

Being impressed with this case, which seemed to me to be merely transferred irritation from the cæcum to the parotids, I was disposed to refer swellings of the parotid, in cases of typhoid fever, to transferred irritation from the glands of Peyer, but I have never witnessed in cases of typhoid fever anything more than a swelling and tenderness of the parotid.

Within the last year I attended a case of severe atonic dyspepsia, in consultation, in which there was also very much of the nervous element.

The stomach became so intolerant of everything except water, that we determined to let it severely alone, and nourish our patient with nutritive enemata; these were composed of beef-tea, brandy, and tr. opium, and were administered every four to six hours. About the fourth day of this procedure the left parotid became painful, swelled so much that the patient could not separate his jaws more than about half an inch, and the socia parotidis seemed very much like going on to suppuration.

Believing that the inflammation of the parotid was likely excited by transferred irritation from the enemata, and the stomach having become somewhat more tolerant, we ceased the enemata. With the aid of poultices the parotid swelling soon began to subside and get well without any suppuration.

I am well aware that inflammation of the parotid occurs in a number of other diseases, as in influenza, but there is associated an aphthous stomatitis, which is, no doubt, the direct cause of the inflammation of the parotid; such also is the case in small-pox.

Inflammation of the parotid occurs in the plague, but in this disease the whole glandular system is very much affected; and so, too, in its congener, typhus fever, inflammation of the parotid is apt to occur.

That very peculiar disease the "mumps," stamps the parotid as an organ differing from all other glands, especially in its sympathies. The above cases are reported to call attention to the fact that the parotid gland takes on inflammation from other causes than septicæmia and the peculiar poison of mumps.

A PRACTICAL POINT CONCERNING EPISTAXIS.

BY GEORGE M. LEFFERTS, M.D.,

PROFESSOR OF LARYNGOSCOPY AND DISEASES OF THE THROAT, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, ETC.

FREQUENTLY recurring, but slight, attacks of bleeding from the nose, specially in children, are a familiar experience to all practitioners. Persistent, prolonged, and repeated hæmorrhages, although rarer, are not unusual, and, finally, ones dangerous in their long continuance and from their frequency are occasionally encountered — hæmorrhages that weaken and exsanguinate the patient; hæmorrhages that recur daily—even several times a day, for weeks and months—and in all classes, be it borne in mind, in subjects otherwise to all appearances well, in short, without apparent demonstrable general or local cause. Such cases, specially the former, are not the exception; they constitute the rule in practice; for the infrequency of epistaxis due to extensive traumatic lesion, and the rarity of that due to deuteropathic causes, will be conceded. Too often have they baffled all well-meant and carefully-studied general, often local, measures, for their relief; and hence, probably, the multiplicity of theories and wealth of advice which may be found in the journalistic literature of to-day concerning their treatment.

We are all familiar with the routine. The simple cause, to which I shall call attention, not being, to say the least, generally appreciated, resource is had to the internal administration of hæmostatics (iron, ergot, belladonna, etc.), or the general application to the nares of styptics (by tampons, pledgets, syringe, soluble bougies, etc.), perhaps to both or all means combined; and, as experience proves, often without success, persistence or recurrence being the rule.

A simple and easily made examination of the anterior nares, with a suitable light and speculum, even without the latter in many instances—an examination that needs neither expert hand nor eye—will reveal the cause of the conditions described, as almost invariably lying in a small, seldom extensive, erosion of the mucous membrane of the cartilaginous septum, just above the point of the former's junction with the skin. The term ulcer cannot be correctly applied to the lesion—certainly not in its earlier stages, and as commonly seen; for although there is of necessity some loss of substance, no marked excavation exists except in extreme cases. Catarrhal conditions may or may not coexist; they probably will, but it must be borne in mind that neither erosion nor ulceration are features of simple nasal catarrh. On the contrary, I believe that these erosions are always the result primarily of the direct mechanical irritation or injury caused by the forcible and repeated removal of the slight crusts of inspissated mucus formed, in the first instance by various accidental circumstances at this point (a slight concavity here is no unusual circumstance), the finger being the common instrument. The epithelial covering of the parts thus once disturbed, the subsequent steps of the process follow. Secretion mixed with blood, in greater or less quantity, readily lodges upon this as upon any irregular surface or point in the nasal passage, dries into a hard crust in the respiratory current, is again removed mechanically, and each time bleeding follows, either directly as the result of the tearing away of the crust, from the slightest cause such as blowing the nose, or even spontaneously, its amount varying with the extent and duration of the lesion, and being dependent upon the unusual richness of the blood supply (small arterial branches) of the septum over other parts. The process thus instituted and continued, naturally follows the usual pathological course of any interference with a wound surface, and, unless timely and judicious treatment cut short its course, the constantly deepening erosion, the constantly increasing crust of blood and mucus, both dependent upon the constant mechanical irritation, can lead to but one result, viz., perforation of the septum, an accident by no means as infrequent as is supposed.

If the cause in these cases of recurrent epistaxis be as I have described, and repeated observations have convinced me not only as to its correctness but likewise of its frequency, the futility of all general constitutional measures, and the uselessness of all imperfectly directed local ones for its relief, is apparent. The secret of success lies in the careful, *direct* treatment of the eroded point; with this care even, patience is also necessary. The condition is often an obstinate one to deal with. The reparative process is slow, and relapse is often the rule. The indications will suggest themselves; acute hæmorrhage, either profuse or moderate, is at once controlled, inspection readily showing its origin, and its location permitting as readily of direct compression or of direct styptic treatment. Foremost in the successive steps then stands avoidance of the habit of direct interference and irritation of the eroded point upon the septum, by the patient, in the removal of crusts, for confirmed habit, this will be proven to be, in the majority of cases, and the prevention of the crust formation upon the abraded surface, by the unremitting use of vaseline, or some form of unirritating ointment. The judicious use, not the abuse, of astringent solutions locally, carefully applied, then play their useful role. Copper will be found to be the best; nitrate of silver is, as a rule, to be avoided. Care, patience, and per-

sistence are the only elements now necessary for the attainment of success.

First impressions may seem to stamp the point that I make as trivial, but I feel assured, having so often been practically convinced of its diagnostic and therapeutic worth, that it will commend itself when, attention being directed to it, familiarity has demonstrated, as it must, its importance.

HOSPITAL NOTES.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

A SERIES OF CASES OF ANEURISM.

(Reported by WILLIAM E. HUGHES, M.D., LATE RESIDENT SURGEON.)

THE number of cases of aneurism treated in the University Hospital in a part of 1881—greater than usually falls to the lot of one hospital in the same time—with the various modes of treatment, and the different results obtained, leads to a belief that a report of them may be interesting. The case of ligation of both common carotids (Case IV.), is especially worthy of attention from its extreme rarity.

CASE I. *Popliteal Aneurism.*—Service of Dr. JOHN ASHHURST, Jr. Wm. G., white, miner, æt. sixty-one; admitted December 12, 1880. Twenty years before had been struck with the sharp end of a pick in the popliteal space. The wound healed, and gave him no trouble for nineteen years. About six months before admission, he noticed a pulsating swelling, which gave slight pain, and interfered somewhat with walking. The swelling grew rapidly, until, on his admission, it had attained to the size of a child's head. The tumor was not well defined, the blood evidently being distributed in the tissues of the leg and thigh. Posteriorly there was a pointed prominence over which the skin was reddened, and the temperature increased, resembling very strikingly the pointing of an abscess, and threatening to burst at any moment. The case was such an urgent one, that any attempt to resort to a cutting off of the blood supply to the aneurism was not to be thought of, and only amputation of the leg was practicable, which was done at the lower third of the thigh. The patient died three days afterwards of exhaustion. On examination of the tumor, the blood was found extravasated into the tissues, dissecting up the intermuscular septa for some distance in the thigh, and pushing before it the fibrous tissue, so as to form a sort of sac. In the posterior wall of the popliteal artery was an orifice three-quarters of an inch long by one-eighth of an inch wide, with rounded, smooth edges, out of which the blood had poured. The sciatic nerve pierced the mass of blood clots, while the popliteal vein had been pushed posteriorly and to the inner side. From the appearance of the orifice, it was evident that the original wound to the artery had cicatrized, and afterwards, consequent on some strain or recurrence of inflammation, the cicatrix had given way, permitting the blood to escape.

CASE II. *Popliteal Aneurism.*—Service of Dr. D. HAYES AGNEW. George D. G., German, white, æt. sixty; admitted May 25, 1881. Impossible to get any connected history of his case. He was a laborer, necessarily exposed to much heavy lifting and many severe strains. His account of the aneurism, was that it commenced as a small swelling, in the right popliteal space, about two years before admission into the hospital, at first not giving him much inconvenience. No history of any strain or injury to which it could be traced. He denied having had syphilis. When admitted, the aneurism (in the right popliteal space), was as large as a closed fist, preventing full extension of the leg, and giving rise to much pain and uneasiness. Pressure on the popliteal vein had caused the leg, below the knee, to become swollen and œdematous to a slight extent. The tumor presented all the characteristic signs of aneurism, pulsation, thrill, bruit, etc. For a few weeks the patient was placed at perfect rest on a low diet and full doses of iodide of potassium, but no improvement making itself manifest, it was determined to try digital compression, the femoral artery below the origin of the profunda femoris being selected as the point to be compressed. Pressure controlled the pulsation in the aneurism perfectly, the tumor becoming relaxed and softer, and diminishing perceptibly in size. Digital compression was maintained steadily at night from about 8 P. M. till 8 A. M. Through the day, pressure was made sometimes by a horseshoe tourniquet, and sometimes by means of the finger. Compression was continued four nights and three days. At the end of the fourth night, pulsation had entirely ceased in the sac, which had become much firmer, and pulsation had developed in two of the articular branches about the knee. Digital compression had been maintained in all fifty-two hours; pressure by the tourniquet, thirty-two hours. The patient was placed in bed with the limb in a slightly flexed position. At the end of three weeks, the tumor had diminished much in size, was hard and firm, and there was a complete absence of pulsation and bruit. The patient was discharged cured.

CASE III. *Popliteal Aneurism.*—Service of Dr. AGNEW. George H., colored, gardener, æt. forty; admitted June 1, 1881. Eighteen months before, in jumping from a ditch, he slipped and fell; as he slipped, he felt a severe pain in his left popliteal space, with a sensation as if something had given way. Shortly afterwards he noticed a small swelling, which grew rapidly and steadily, and was attended with pain. He had not had syphilis. On admission, the aneurism (in the left popliteal space), had attained the size of two closed fists, and was attended with pulsation, thrill, and bruit. The leg was partly flexed, and could not be moved. Below the knee it was markedly swollen and œdematous, though pulsation in the arteries of the foot was distinguishable. Pressure by Esmarch's bandage was first resorted to, the bandage being applied from the foot up to the lower edge of the tumor, then from the upper edge of the tumor to the groin. It was kept on an hour, the patient being placed slightly under the influence of ether. At the end of the hour the bandage was removed, when it was found that pulsation was as vigorous as ever. After the failure of this treatment, and owing to a difficulty in obtaining aid in making digital compression, Dr. Agnew determined to ligate the femoral artery at the apex of Scarpa's triangle, the carbolized animal ligature being used. Pulsation and bruit in the tumor ceased, and it became flaccid. The wound at first healed superficially, but in a few days suppuration in the deeper parts became manifest, and it was reopened. The swelling of the leg increased, and marked tenderness developed over the aneurismal tumor. A few days after the operation, pleurisy, with some effusion, developed in the left side, but soon subsided. Sixteen days after the ligation, secondary hæmorrhage occurred from the proximal end of the artery, but was controlled, before much blood had been lost, by ligating the artery in the wound above the seat of the original ligature. After this the swelling in the leg gradually increased, and blebs formed on the great toe. Ten days after the hæmorrhage, pleurisy reappeared in the left side, running on into pneumonia of the left lung, and the patient died about five weeks after the original ligation. No post-mortem examination was made of the aneurism.

(To be concluded.)

MEDICAL PROGRESS.

RESECTION OF THE ANKLE-JOINT FROM THE FRONT.—DR. C. HUETER describes in a recent number of Langenbeck's *Archiv. f. Klin. Chirurg.* a method of excising the ankle-joint, which he has recently practised with success. It was suggested by the consideration that it is from the front that the best view of the joint surfaces can be obtained and the removal of carious foci of bone most readily achieved. The difficulties in the way of such a proceeding are, however, evident, and previous to our recent experience of the successful suture of severed tendons and nerves, they were insuperable. But this experience has enabled Hueter to carry out his desired procedure. He makes a transverse incision from the back of one malleolus to the back of the other, places a double ligature on the anterior tibial artery, and cuts the vessel between, and divides its companion veins and nerves. The tendons of the tibalis anticus and extensor longus pollicis are cut, and that of the extensor communis digitorum drawn aside or cut as may be necessary. The capsule of the joint is then opened from the front, and the diseased surfaces of bone sawn off or gouged out. The real difficulties of the operation now commence. The divided nerves—anterior tibial and musculo-cutaneous—are united by fine sutures through the paraneurotic loose connective tissue. The cut tendons are in the same way joined, not end to end, but overlapping each other, so that the uninjured peri-tendinous tissue around the two ends is in contact. Of course every precaution must be taken to secure primary union of the wound.—*Lancet, Dec.* 17, 1881.

SEPARATION BETWEEN THE PATELLA AND ITS TENDON.—MR. RUSHTON PARKER reports in the *British Medical Journal*, for December 17, 1881, a case of ununited wide separation between the patella and its tendon, in a boy aged twelve years, which was cured by incision and antiseptic suture with copper wire. The patella was firmly attached to its tendon, though one inch higher up than the one on the opposite side, and muscular motion was restored; passive motion was not employed in the treatment.

OVARIOTOMY DURING PREGNANCY.—At the meeting of the Royal Academy of Medicine of Belgium on November 26, Dr. GOLENVAUX related the particulars of two cases of ovariotomy, which he had performed successfully during pregnancy. The two patients were present at the meeting. In the first case the operation was performed in the end of June, 1877, for a right ovarian cyst, the patient being then five and a half months gone with child. In the middle of October an infant was born, which weighed 3235 grammes. In the second case, also, the right ovary was removed, and at about the same period of pregnancy. The operation was performed on the 15th of September last. The patient has since then been very well, and the child gave signs of life about the middle of October. The pregnancy is running the usual course, and everything betokens the probability of a good confinement.—*Lancet, Dec.* 17, 1881.

CLOGGING OF THE INSTRUMENT IN LITHOTRITY.—In the *Maryland Medical Journal*, for January 2, 1882, Dr. ALAN P. SMITH reports an instance in which, after crushing a hard mulberry calculus in the bladder of a man aged sixty-three, it was found that the jaws of the instrument were clogged, and could not be closed, an interval of three-fourths to one inch remaining between the blades. After numerous attempts at closure, the instrument was forcibly withdrawn through the urethra, the bladder washed out, and the patient placed under opium. A good deal of hæmorrhage and pain followed, with ecchymosis, but no urinary infiltration. The patient did well after the first day.

LOCOMOTOR ATAXY FOLLOWING SMALL-POX.—At a general meeting of the Harveian Society of London, Dr. C. G. HENDERSON read the notes of a case of confluent small-pox followed by ataxy. The patient, George A., aged thirty-five, was admitted to the St. Pancras Tent Hospital on May 27, 1881. His temperature, which had ranged between 100° and 102° Fahr., rose suddenly on May 31, reaching in a few hours 107.8° Fahr., and he was then immersed in a bath at a temperature of 68°, for fifteen minutes. His temperature was then 96°, but it rose gradually in the course of the next eighteen hours to 104.4°, and the bath was repeated. No hyperpyrexia or other complication followed, but convalescence was much protracted, large bullæ having formed on the soles of both feet, leaving scabs which separated very slowly. On the 18th of July, when he began to get up, he suffered from numbness and tingling of the feet, legs, and hands; the knee-jerk and ankle-clonus, as well as the skin reflexes, were absent, and he lost his balance when the eyes were closed. No myosis was present. After leaving the Tent Hospital, he attended as an out-patient at University College Hospital. He slowly gained power in his legs, but, when last seen, the knee-jerk was still absent. Dr. Henderson referred to similar cases recorded by Landouzy and others, and considered the lesions causing the patient's symptoms were probably analogous to those found in diphtheritic palsy, and other forms of paralysis noticed after acute diseases. They differed from those of true locomotor ataxy in the more favorable course which they took, ending, in the majority of cases, in recovery.—*British Med. Journ.*, Dec. 24, 1881.

INFLUENCE OF THE CHOROID ON THE ACUTENESS OF VISION.—At the meeting of the *Académie des Sciences*, on December 5, 1881, M. FANO presented a note on this subject. Most physicists and physiologists have only attributed to the choroid the role of absorbing, by its pigment layer, the luminous rays which pass through the retina, in order to prevent their being reflected forward again from the back of the eye. The choroid is generally compared to the black lining usual in optic instruments. M. Fano, however, believes that the choroid has a more important function. Inasmuch as it is essentially a vascular organ, it has for its function the transferring to the retina the greater part of its nutritive elements, the central artery of the retina, and its branches being insufficient to supply so marked a functional activity.—*Gaz. Méd. de Paris*, Dec. 24, 1881.

AN UNUSUAL CASE OF INTESTINAL OBSTRUCTION.—At a recent meeting of the Northumberland and Durham Medical Society, an interesting case of obstruction of the bowels was recorded by Dr. DRUMMOND as having occurred in his hospital practice. The patient, a male, aged fifty-four, was admitted into the Newcastle-on-Tyne Infirmary for constipation, vomiting, and suppression of urine. The first symptoms—constipation, with pain in the right hypochondrium, especially after eating—had been noticed eight weeks before; and, for nearly three weeks, there had been occasional vomiting and complete obstruction. The usual therapeutical manœuvres failing to give relief, and the patient's condition becoming urgent, it was deemed expedient to explore the abdominal cavity; and this Dr. ARNISON, the senior surgeon to the hospital, proceeded to do by abdominal section. An incision was made to expose a mass which could be felt through the abdominal walls, occupying the position of the ascending colon. The

peritoneum covering the mass was livid, and, from its appearance and relations, was taken for intestine and opened. There was found a tubular cavity containing dark, loose blood-clot, of offensive odor; and, contained also within this cavity, at about the position of the hepatic flexure of the colon, was a calculus, of the size and shape of a large nutmeg. The condition of the patient, who was observed to be sinking, and who shortly afterwards died, prevented further exploration. At the post-mortem examination, Dr. Drummond discovered an aneurism of the hepatic artery, which had ruptured its walls, and the contents of which, on becoming diffused, had passed down behind the mesentery, and, pressing upon the ileum a few inches above the cæcum, had thus brought about complete occlusion of the gut. The calculus, a biliary one, was evidently derived either directly from the gall-bladder or from one of the hepatic ducts. A circular space, two and a half inches in diameter, was absorbed on the under surface of the liver, corresponding to the position of the gall-bladder, which, at the post-mortem examination, could not be found. The case, we believe, is almost unique in the annals of abdominal surgery.—*Brit. Med. Journ.*, Dec. 31, 1881.

PORRO'S OPERATION.—A patient, aged thirty-six, nine months pregnant, who had been sixteen hours in labor, was admitted to Queen Charlotte's Lying-in Hospital, at 10.20 P.M., on December 10. Her lower limbs exhibited extreme rickety deformity, and the conjugate diameter of the brim of the pelvis measured one inch and a half. The os uteri was dilated to the size of a shilling-piece, and the pains were feeble and unfrequent, and the patient's strength not much impaired. After consultation with Dr. Hope, Dr. Percy Boulton, and Dr. Brodie, Dr. Grigg performed Porro's operation, in which he was assisted by Sir W. MacCormac and Dr. Boulton. A living child was extracted. The mother did well up to twenty-four hours after the operation, when she died suddenly. The post-mortem examination by Dr. Allchin revealed incipient peritonitis, but nothing to account for the patient's sudden collapse was discovered, and it was inferred that death resulted from the shock of the operation.—*British Med. Journ.*, Dec. 17, 1881.

NERVE PROSTRATION AND HYSTERIA CONNECTED WITH UTERINE DISEASE.—In the *Lancet*, for May 28 and June 11, Dr. W. S. PLAYFAIR reported four remarkable cases of neurasthemia, growing out of old-standing uterine disease, entirely cured by the systematic treatment, brought under the notice of the profession by Dr. S. Weir Mitchell, in his brochure on "Fat and Blood." In the number of the same journal for December 10, 1881, he states that in the past six months he has had many opportunities of carefully studying this subject with the result of giving him daily increasing confidence in Dr. Mitchell's method as an invaluable aid in managing such classes of disease.

TREATMENT OF DETACHMENT OF THE RETINA BY GALVANO-PUNCTURE.—Detachment of the retina, according to Dr. ABADIE, is most frequently dependent upon a local cause, as it occurs ordinarily suddenly in cases of myopia associated with no diathesis whatever. It can therefore be treated by purely surgical means.

Clinical observation, pathological anatomy, and experiments on animals show that the retina forms adhesions to the choroid wherever there are areas of spontaneous or provoked choroido-retinitis; if, therefore, such adhesion can be produced artificially, it can be hoped that the retina will be fixed to the underlying membranes. In order to produce this result, Dr. Abadie punctures the sclerotic and choroid with a delicate platinum knife, heated by the galvanic current, as far behind the ciliary region as possible. The ocular membranes being thus perforated, the sub-retinal fluid escapes, and an adhesive inflammation is produced which maintains the retina in place. This method of treatment has been employed in eight different cases: in six instances of extensive old separation only slight benefit was produced, but in two cases, where the detachment was limited, most satisfactory results followed. In no case was the reaction too violent, or have any unpleasant consequences occurred.

Struck by the considerable reduction of interocular tension which remains after galvano-puncture of the eye, Dr. Abadie has made use of this method of treatment, with the happiest results, in cases of glaucoma which resist treatment by iridectomy and sclerotomy. —*L'Union Médicale*, Dec. 6, 1881.

EPIDEMIC OF ECTHYMA IN SMALL-POX CASES.—M. RENDU has seen in the Tenon Hospital a number of cases analogous to those recently described by M. du Costel. M. Rendu, however, believes that the eruption is more closely allied to pemphygus than ecthyma. In 1870, during the epidemic of variola, M. Rendu also saw this eruption occur in the cases in St. Antoine Hospital. In some cases the appearance of this complication does not modify the course of the variola; in others, as soon as the ecthyma appears, the temperature rises as much as two degrees or more. The general condition of the patient may be aggravated, and fatal septic accidents may occur from this secondary eruption.—*Bull. Gén. de Thérapeutique*, Dec. 15, 1881.

RELATIONS OF ANGINA PECTORIS TO DIABETES.—At the meeting of the *Académie de Médicine*, held on the 22d of November, M. VERGELY, of Bordeaux, read a paper with the above title, of which the following are the conclusions:

1. The attack of angina pectoris may be associated with diabetes.
2. The attack may be simple, or accompanied by intermittent neuralgias.
3. It can occur independently of any cardiac affection.
4. In attacks of angina pectoris, the urine should always be examined to determine whether the neurosis or neuralgia is not associated with diabetes.—*Bull. Gén. de Thérapeutique*, Dec. 15, 1881.

HOSTILITY TO THE LOCAL USE OF ATROPIA AND DUBOISIA.—In the *Maryland Medical Journal*, for December 15, 1881, Dr. JULIAN J. CHISOLM reports a case of a woman aged seventy, who, after having for a long time systematically made use of atropia after an operation for cataract, suddenly developed a hostility to its action; its use four times being distinctly followed by severe facial erysipelas. A four-grain solution of duboisia was then substituted for the atropia, with the effect of producing decided mental disturbance.

THE MANAGEMENT OF FEVER IN CHILDREN.—The antipyretic treatment of fever in children by cold water, quinine, and salicylic acid, is the subject of some remarks by Dr. FÖRSTER (*Jahrb. f. Kinder*, xvi.) The indication for their employment may be stated to be when danger supervenes from either the height or the duration of the pyrexia. Accurate observations are still wanting on the effect of cold baths, but their therapeutic value is greater than in adults, and their action more intense, since the body-surface is greater in proportion to the body-volume in children. There appears to be considerable difference between rectal and axil-

lary temperatures after cold baths, and a marked fluctuation for some time afterwards. In cases where baths are not applicable, cold packing, sponging, or spraying may be employed; but the effect is not so marked. Quinine and salicylic acid have a more permanent effect than cold water, and should be given to children in doses much larger relatively to their body-weight than is the case in adults. Their use is frequently followed by vomiting; and in those diseases attended by failure of the heart's action, as diphtheria, quinine is to be preferred.—*London Med. Record*, Dec. 15, 1881.

Battey's Operation for Intermenstrual Pain.—An interesting and instructive case is recorded by Fehling in a recent number of the *Archiv für Gynäkologie*. The patient was aged thirty-one, married for eight years, but sterile. Menstruation was painless, but the patient said that she suffered from severe attacks of pain, which came on from fourteen to sixteen days after one menstrual period, and lasted till three days before the beginning of the next. The cervix uteri had been incised and dilated; the uterus had been depleted; the patient had tried one of the bath cures,—but without benefit. She had had an attack of scarlet fever, during which the pain was quite absent. It was thought that the pain was connected with the maturation of Graafian follicles, and therefore spaying was advised; Professor Hegar concurring with Dr. Fehling in this recommendation. The operation was performed in June, 1880, both ovaries being completely removed; and the patient recovered. The ovaries were thought to possess an unusually tough and hard tunica albuginea, and the number of follicles was considered unusually small; but examination, both with the naked eye and the microscope, failed to detect anything else abnormal about them. The patient left the hospital four weeks after the operation, and remained well for six or eight weeks later. Then the pains began to return, and soon became as bad as ever. Hæmorrhage, similar to that of menstruation, also recurred. The patient, therefore, was not benefited by losing her ovaries. We have had occasion to speak strongly on the wrong done to medical science by authors who rush to announce their cases as cures before there has been time to ascertain whether the ultimate result has been beneficial or not. This case shows the necessity for caution before assuming that benefit immediately following extirpation of the ovaries will be permanent. Only in cases which have been watched for a long time can anything be safely said as to whether they have been cured or not.—*Med. Times and Gazette*, Dec. 10, 1881.

Treatment of Phimosis by Dilatation.—In a recent clinical lecture delivered at La Pitié, Prof. Verneuil recommends the treatment of phimosis by dilatation, as first advocated by Nélaton, rather than by circumcision. His mode of operation is very simple. He anæsthetizes the patient, as it is advisable to proceed as slowly as possible, and to obviate the pain inherent to the operation. He draws out the prepuce, and commences by introducing a grooved director between the prepuce and the glans, and then passes a second grooved director along the groove of the first. In this way a commencement of dilatation takes place, and he then introduces a common dressing-forceps, opens it, and withdraws gradually, distending the prepuce just as the anus is dilated by a speculum. Since he has had recourse to this procedure he has never yet met with a failure. All that can happen is a slight rupture of the preputial mucous membrane, giving rise to a few drops of blood. When the prepuce thus dilated is everted, the glans is washed with some carbolized water. If the dilatation has been very considerable, the prepuce can be closed over the glans. If not, there will be a paraphimosis, which should be dressed with lead lotion, without any fear that gangrene of the glans or the penis will be produced by strangulation. Still, gangrene of the glans does occasionally take place, without any satisfactory explanation being possible.—*Med. Times and Gaz.*, Dec. 10, 1881.

Porro's Operation, Successful Result for both Mother and Child.—Werth, in the *Arch. f. Gyn.*, xviii., s. 293; reports this case in which Cæsarean section had been twice before performed on account of a highly contracted pelvis, and in whom he performed Porro's operation without difficulty, and according to Veit's advice, before the commencement of labor. The child was born with left-sided facial paralysis. The pedicle was treated outside of the peritoneum, and the general principles followed which are advised by Hegar (*Ab. f. Gyn.*, 1880, s. 265). In order to prevent septic infection, the pedicle was covered with a thick coating of benzoate of soda, after its raw surface had been superficially charred with the thermocautery, and wiped with a ten-per-cent. solution of chloride of zinc. By this means suppuration was prevented, there was no febrile reaction, and the patient was able to leave her bed five weeks after the operation.—*Centralb. f. d. Med. Wissen*, Dec. 10, 1881.

Boracic Acid in Fetid Sweating.—Dr. George Thin speaks in the highest terms in the *Practitioner*, for December, 1881, of the use of boracic acid in cases of offensive sweating of the feet. He employs a solution of boric acid in glycerin incorporated with a fatty basis of white wax and almond oil; this gives a soft homogeneous cream, free from all irritating crystalline plates and quite permanent.

A New aid to the Diagnosis of Unilateral Disease of the Kidney.—Dr. M. Gluck sends a communication to the *Centralblatt für Chirurgie* for December 10, in which he refers to a new method of discovering in a case in which removal of one kidney seems advisable, whether or not the kidney of the opposite side retains any secreting substance. He proposes that as small an incision as possible shall be made over the kidney to be removed, and that then the ureter shall be sought, and compressed either by a temporary ligature or the application of a pair of forceps. When this is done, some material which is certain to make its appearance rapidly in the urine, such as ferrocyanide of potassium or iodide of soda, is to be injected subcutaneously, and successive drops of urine are to be tested for the presence of the drug by means of a catheter introduced into the bladder. It seems to be suggested that the appearance of the material injected in the secretion of the opposite kidney will be a justification to proceed with the operation, though we must confess to certain misgivings on this head. We can conceive a very imperfect kidney—that is to say, one that would be far from sufficiently healthy to fulfil the whole requirements of the body—which might still secrete enough of the injected material to allow of its being rapidly discovered in the urine; and thus it appears to us that the test might give undue confidence to the operator. If, after a sufficient time has been allowed to elapse, the urine from the presumably unaffected side gives no reaction, it is advised to release the ureter of the diseased side, and test the urine coming from it. The writer adds that the experiment could not be made in cases where, owing to anatomical complications, the ureter of the affected kidney could not be reached, and that it would prove delusive if there happened to be a horse-shoe kidney, the existence of which would, of course, seri-

ously interfere with the diagnosis under any circumstances.—*Med. Times and Gaz.*, Dec. 17, 1881.

RÖTHELN.—Dr. C. M. JONES describes a number of cases of this disease, and gives an excellent table in which the clinical history and symptoms of rötheln and measles are contrasted. He believes that it should be regarded as a specific exanthem:

1. Because of its contagious reproduction of itself.
2. Because it does not afford immunity from any other disease, nor does any other disease afford immunity from it.
3. Because of the pecularities of the eruption.
4. Because of the pecularities of the temperature.
5. Because of the absence of desquamation.
6. Because of the absence of sequelæ.—*Boston Med. and Surg. Journ.*, Dec. 29, 1881.

OPTICO-CILIARY NEUROTOMY AS A SUBSTITUTE FOR ENEUCLEATION.—Dr. JOSEPH A. WHITE objects to the method of optico-ciliary neurotomy generally recommended for the prevention of sympathetic ophthalmia, on account of the difficulty in readjusting the recti muscles when cut and the danger of an oblique muscle being unintentionally divided. His operation, which he has three times successfully employed, is performed as follows: A meridianal incision is made through the conjunctival and subconjunctival tissues from the upper border of the external rectus to the outer border of the superior rectus, thus exposing the sclerotic. A strabismus hook is then inserted under each of these muscles, and with them an assistant pulls the eye down and towards the nose. A small lid elevator is then hooked under the upper lip of the incision and drawn up, thus making a large opening through which the curved scissors can be passed behind the eyeball, and the optic and ciliary nerves cut. Knapp's double hook is then inserted into the posterior part of the sclerotic and, without any trouble, the cut end of the optic nerve and its surroundings are exposed to view at the incision. The sclerotic is then carefully cleaned with the scissors—thus cutting away sections of the optic and ciliary nerves. As long as any blood oozes from the opening, it is kept open. When this ceases, a conjunctival stitch is put in, and cold-water dressing applied.—*Virginia Med. Monthly*, Dec., 1881.

ARTERIO-VENOUS ANEURISM.—In the *Virginia Medical Monthly* for December, 1881, Dr. E. L. KEYES publishes a valuable historical paper on *Arterio-Venous Aneurism*, in which he details a case unsuccessfully operated on by Annandale's operation, the patient dying of septicæmia. Dr. Keyes believes that in a young anæmic case it would be better to use palliative treatment, and not undertake any operation. If, however, an operation is undertaken, amputation should be performed antiseptically if all hæmorrhage cannot be controlled absolutely. He also draws attention to the varying pathological structure of an arterio-venous aneurism.

ALBUMINURIA IN FEBRILE DISEASE.—From an elaborate study of this subject, Dr. EMIL ECKSTEIN concludes that febrile albuminuria is dependent upon a local process in the kidneys, especially in the epithelium, of an inflammatory nature, and that this process is dependent upon an infection of the kidney caused either by the actual passage of parasitic organisms or by the inflammatory action of the poisonous principles in solution. An acute nephritis can also be produced by this infection, and Dr. Eckstein believes that acute infectious nephritis and the febrile affection of the kidney are only different grades of the same process, or, in other words, that the kidney affection dependent upon fever is merely an abortive form of acute infectious nephritis.—*Deutsche Med. Woch.*, Dec. 17, 1881.

THE EFFECTS OF GYMNASTICS.—M. ROUHET has developed in his thesis the researches undertaken in M. Marey's laboratory, on the general influence of gymnastics and muscular effort. Under all forms of muscular exercise, as has been long known, the rhythm of the heart and respiration are accelerated, and the temperature increased. While the cardiac movements are increased there occurs also a dilatation of the peripheral vessels, probably dependent upon the increase of temperature, and as a consequence of the dilatation, there is an increased loss of heat. It is by this means that the animal heat remains within normal limits. The respiration becomes slightly accelerated, but especially changed in rhythm, the amplitude being deeper than before. By these deeper and more frequent respiratory movements there is an increased exhalation of water from the pulmonary surface, and an increased loss of heat through the expired air. In addition, on account of the more marked thoracic aspiration, there is a facilitated and more rapid pulmonary circulation, and, as a consequence, increased gaseous interchange. M. Marey insists that increase in the amplitude of the respiratory movements does not last only during the time of exercise, but that individuals who practice gymnastics regularly have as a consequence a permanent increase in their inspiratory vigor.—*Revue Scientifique*, Dec. 10, 1881.

EXCISION OF THE KNEE IN EARLY LIFE.—From a paper on this subject, Dr. WILLIAM STOKES draws the following conclusions:

1. Excision of the knee should not be looked upon as a last resource, but should be undertaken, if possible, before any profound organic changes take place.
2. Expectant treatment, to be efficient, must be undertaken at an early stage of the disease, and extend over a period of at least two years.
3. No better result than ankylosis can be looked for by this method.
4. In a patient with a predisposition to secondary tuberculous developments, the possibility of the recurrence of the disease after expectant treatment must be borne in mind.
5. In cases attended with prolonged suppuration, the chances of the occurrence of visceral, especially renal disease, must not be lost sight of.
6. Where the skin is unbroken, the disease limited, an efficient method of fixation applied, and a rigid system of antiseptic dressing of the wound adopted, primary union may, in the majority of cases, be anticipated.
7. When these latter conditions are fulfilled, excision of the knee-joint cannot be longer regarded as the formidable procedure it was formerly held to be.
8. The alleged unfavorable results of excision of the knee-joint in early life are opposed to more extended clinical experience.—*Brit. Med. Journ.*, Dec. 10, 1881.

SALIVARY SECRETION FROM CONJUNCTIVAL IRRITATION.—The interesting work of Dr. ASCHENBRANDT proves that all irritating fluids when applied to the conjunctiva, produce a secretion of saliva in carnivorous animals, and he has worked out the complex path of nervous communication. He has also found that atropia inhibits this salivary secretion; that the secretion of the parotid gland is under the control of the glasso-pharyngeal nerve; that the sympathetic is not included in the nerve communication, and that in all instances the secretion is produced by a reflex action.—*Deutsche Med. Wochenschrift*, Dec. 10, 1881.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JANUARY 28, 1882.

SMALL-POX.

REPORTS of the spread of this disease continue to appear in the daily press, and the National Board of Health has formally declared it to be epidemic in the United States.

This formal declaration is necessary to permit of the use of the fund set apart by the act making appropriations for the use of the Board during the current fiscal year, as follows: "For aid to local quarantine stations, and for aid to Local and State Boards of Health, to be used in case of epidemics, $100,000."

Probably the reason for the delay on the part of the Board to take this action has been that it has, until quite recently, received no requests from either local or State Boards for pecuniary aid, and that it has not considered it prudent to make available a fund guarded by such a special proviso, until it should have some evidence that it was actually needed.

Now, however, we understand that at least one such demand has been made, and that there is a prospect of others. In our last issue we referred to the desirability of having every emigrant to this country protected by vaccination. At the present moment this is, of course, more necessary for the protection of the emigrants themselves than it is for that of our own citizens, seeing that the disease is already prevalent in those places to which emigrants usually first resort; but the principle is the same in either case. We are glad to learn that the great steamship companies are about to deal with the matter on common-sense business principles, and insist that all emigrants shall be vaccinated at the place where they embark for this country, and thus prevent the delay which would otherwise be required at the quarantine stations on this side.

The result of all this will be that when we have passed through the present epidemic, we shall have a system of protection from another invasion of the disease from abroad; a system by no means perfect, it is true, but still a vast improvement on the "happy-go-lucky" fashion in which we have managed the matter heretofore.

INTERNATIONAL COPYRIGHT.

IN our last we briefly called attention to the condition and prospects of our home medical literature as it has flourished thus far in the absence of international copyright, and we showed that the lack of the stimulus which such a measure is expected to afford had not prevented the satisfactory development of the literature of our science. The fact is that the influence of such legislation upon production of this nature is much less than is popularly supposed. Professional men, unlike professional literateurs, write from many motives, among which that arising from expected pecuniary rewards is frequently, perhaps, the least. Many labor from an honest ambition for fame, or from a sense of duty to their fellows; many others, because a well-written and successful work is one of the surest aids to professional success; others, again, blessed or cursed with the literary temperament, find in composition a congenial employment for the leisure hours, which, during the earlier years, at least, of professional life, are too numerous in the experience of nearly all of us. In a commercial sense, therefore, the supply is not regulated by the demand; and even as the greatest pecuniary offers would not tempt some men to write, so the prospect of unpaid labor will not deter others.

How little, in fact, the commercial spirit has to do with these matters is shown by comparison of the value of literary property in England, whose medical writers, protected by copyright, have virtually no foreign competition to dread, with that of America, where we are constantly assured that native literature cannot flourish in consequence of its exposure to competition with uncopyrighted English work. The fact is that medical writers in America are paid fully as well as, if not better than, their English brethren. A very large proportion of all the medical works which are issued from English presses are published "on commission,"—that is, at the expense and risk of the author; and it is perfectly fair to assume that in a majority of cases the author finds that the returns do not equal the outlay. Publishing "on commission" is far less common in this country. In the case of successful works the receipts of authors here are apt to be larger from the fact that they are usually paid by a "royalty,"

while in England the custom prevails, when books are not issued on commission, of a purchase outright of the copyright by the publisher, in which case the interest of the author ceases, unless he may receive some small payment for the revision of subsequent editions. There can be no doubt that the sums received by the late Dr. Dunglison and by the authors of the *United States Dispensatory* exceed the aggregate paid to the most successful English authors of medical works. As regards journalism, we think that we can assert with safety that the compensation paid by the NEWS for original contributions is fully as large as, if not larger than that paid by any English medical periodical.

We therefore believe that those will be disappointed who look for any very marked improvement in the status of American medical authors, and any very decided stimulus to the development of American medical literature, from the adoption of an international copyright. Nor, on the other hand, do we, for the same reasons, anticipate any very great increase in the prices of medical books from such cause, provided the measure be such as to insure the manufacture of books in this country in the styles and forms which experience has shown to suit our markets. At the same time, there is a principle of equity involved which must render all right-minded men desirous of seeing literary property properly protected and the rights of the author recognized.

As our readers may not be familiar with the existing condition of the question, we may briefly state that for some time past negotiations for a treaty with Great Britain on this subject have been carried on by our minister in London, Mr. Lowell, under instructions from Washington, and it is understood that substantial agreement has been reached upon the principal features of a convention. These negotiations have been delayed, first, by the change of administration last March, and then by the assassination of President Garfield, leading to the recent withdrawal of Mr. Blaine from the State Department. What are the views of the new Secretary, Mr. Frelinghuysen, we are not advised, but it is not likely that he will take a different view of the matter from that of his predecessors. One difficulty, however, in the way of an international copyright convention, is the fact that the Constitution intrusts to Congress exclusively the power of regulating copyright; so that the framing of a convention on this subject is a usurpation of the executive over the legislative department of the government, unconstitutional in itself, and requiring, to give it vitality, legislation by the bodies whose privileges have been overridden, who will thus be indisposed to grant such legislation, and who will be amply justified in refusing to sanction so evil a precedent. Besides this, there is the objection that a treaty is framed for a definite term of years, and is unalterable even though its provisions should be found by either party to be unwise in their details.

To remove these sources of opposition to the measure, a bill, containing nearly the same provisions as the treaty, was introduced in the House of Representatives last winter by the Hon. W. D. Kelley, of Pennsylvania. It is, however, more comprehensive in its scope than the treaty, inasmuch as it enables the authors of all countries which grant reciprocal privileges to American authors, to obtain the advantages of copyright here, and is thus not limited to England. At the meeting of the International Literary Congress, at Vienna, in September last, where International Copyright formed the leading topic of discussion, the view was prominently urged that copyright ought not to be the subject of international conventions, which might be terminated at any moment by war, but that each country should legislate for the benefit of foreign as well as of native authors. This view, which is carried out by Mr. Kelley's measure, was not pressed to action, for the purpose of not interfering with the proposed Anglo-American convention, the success of which was regarded by Congress as more certain than we think it likely to prove. The French and German delegates to the Congress, moreover, were loud in their demands that any convention between the United States and Great Britain should be followed by others with their respective countries. These demands are likewise met by Mr. Kelley's bill, which would place it in the power of all foreign governments to give their citizens the benefit of American copyright.

As in the recent organization of Congress, Mr. Kelley has been placed at the head of the Committee on Ways and Means, and is thus made one of the leaders of the House, there would appear to be a better prospect than ever before of accomplishing some practical legislation on this subject. In this, we would call upon our readers to assist. There is no profession more influential than the medical, when it chooses to make itself heard; and if all its members who feel an interest in this question would correspond with their members of Congress, they could do much to overcome what is really the great obstacle to action—the lack of interest felt in the matter by many members of Congress, and the pressure of business which renders it so difficult to get any measure fairly before the House for discussion.

THE LAW OF INSANITY.

THE act recently introduced into Congress by Mr. Springer, and said to have been drawn by David Dudley Field, is intended to define insanity in criminal cases, occurring within the jurisdiction

of the United States. The ability to distinguish between right and wrong has always been held by lawyers as the proper test of responsibility for those mentally unsound. In the proposed law, that "defect of reason" necessary to constitute irresponsibility, consists, "first, not to know the nature and quality of the act he was doing; or, second, not to know the act was unlawful or wrong." In other words, an imbecile who cannot appreciate the nature of the criminal act he commits, or an insane man who cannot discriminate between right and wrong, are equally held irresponsible before the law. This definition will not be assented to by alienists, who have always maintained that the conception of criminal responsibility by lawyers was much too sweeping, and included an important group of cases which ought to be exempt.

To illustrate—there are those who suffer from delusions of hearing, insane who hear voices, and receive commands from God to do acts in contravention of the laws which they know to be wrong, but which they take a delight in doing, because acting under superior power. According to the terms of the proposed act, such an intellectually insane person would be held amenable. It may be said, however, that such insane are peculiarly dangerous, and that as their existence is a constant menace to society, they should suffer the penalty for their acts. The restraint provided for in the last section, namely, confinement in an asylum, more humanely disposes of such cases. It may be admitted that, in general, the legal test will more surely include the criminal. If any latitude of construction is permitted, the door is open to every loose definition, and the impulse to commit a crime, as in the case of Guiteau, comes to be held as an insane impulse which overthrew the reason. The manner of Guiteau's "inspiration" is very different from those delusions, in which the insane man hears a voice which compels him to obey. Guiteau's "pressure" is the conception which an ignorant lawyer would be likely to form of that kind of delusion which forces some insane to commit terrible crimes. In the case of the really insane, the act follows quickly on hearing the command; the obedience is immediate and unquestioning, because the command is clearly heard and is imperative.

SPONGE-GRAFTING.

A SUBJECT of both practical and pathological interest, to which attention is called in the *Edinburgh Medical Journal* for November, 1881, by Dr. D. H. Hamilton, the accomplished pathologist to the Edinburgh Royal Infirmary, is that of promoting the cicatrization of large ulcers and surgical wounds, by accurately fitting a piece of sponge into the deficiency, which, like a layer of fibrinous lymph or a clot of blood, forms a passive porous agent for the building up of a mass of cicatricial tissue. His method, and the result obtained, will be best understood by the following abstract of the first experiment:

A circular ulcer of the leg, which was five inches in diameter, and from half an inch to three-quarters of an inch deep, and the floor of which was still the seat of a small slough of connective tissue, was filled with one large piece and several small pieces of decalcified and carbolized very fine sponge, over which were retained a bit of protective and lint, soaked in a one-to-twenty solution of carbolic acid in glycerin. As there was marked putrefactive odor at the expiration of forty-eight hours, the wound was irrigated with a one-to-forty carbolic solution, and this was continued throughout the progress of the experiment. On the third day the sponge was found to be adhering to the granulating surface; on the fifth day its interstices were filling with germinal tissue, and its edges seemed to be dissolving as it became infiltrated by the new tissue; and from this time onwards, the reparative material continued to grow into the sponge. As soon as its framework was filled, epithelium spread over it; and, at the expiration of five months from the commencement of the experiment, it had entirely vanished, and there was merely a superficial, healthy, granulating surface, an inch and a half in diameter. Hence, in this case, despite the fact that the wound was in a putrescent condition, the sponge, like a blood-clot, became filled with embryonal tissue and bloodvessels, which grew into it from the edges and bottom of the ulcer, and which ultimately caused the sponge to disappear, leaving an organizing mass, out of which the gap was reconstructed.

In the remaining experiments, which were conducted upon ulcers and the large wound left by the amputation of the female breast, the process of healing was equally slow, and this seems to be the only objection that can be urged against the general adoption of the method. On the other hand, it possesses the great advantage of furnishing a non-contractile cicatrix, so that it may be resorted to for the healing of large deficiencies in which a soft and pliant new tissue is deemed desirable.

The conditions essential to the successful performance of sponge-grafting may be summarized as follows:

First. The sponge should be very fine and porous, and be decalcified by immersion in dilute nitro-hydrochloric acid, the excess of the acid being subsequently removed by washing in solution of potassa, and then be rendered antiseptic by steeping it in a five per cent. solution of carbolic acid.

Secondly. The antiseptic sponge should be made to fit the wound very accurately, and should rise a

little higher than the level of the skin. It should be kept aseptic throughout the treatment, or at any rate until it is entirely replaced by a healthy granulating tissue, by a piece of protective, and a one-to-twenty solution of carbolic acid and glycerin. If at any time there is a distinct putrefactive odor, the wound should be irrigated with a two-and-a-half per cent. solution of carbolic acid.

Thirdly. The wound itself, at the outset, should be in a healthy condition, although the presence of a certain amount of foul slough is not a bar to success, as we have seen in the abstract of the first experiment.

Dr. Hamilton thinks that a solid framework for the formation of new bone after operations for necrosis may be found in charcoal or calcined bone. In view of the startling results obtained by the insertion of sponge amid living tissues, which tend to overthrow the old theory of the pernicious action of all foreign bodies when retained in wounds, the suggestion is worthy of adoption, and we trust that we may soon hear that it has been submitted to practical tests by hospital surgeons.

THE UTILITY OF THE SALICYLATES IN RHEUMATISM.

MUCH discussion, during the month of last December, was had in England as to the real value of the salicyl compounds in acute rheumatism. In the *Lancet* for December 31, 1881, we find a report based on twelve hundred cases of this disease treated in Guy's Hospital by different physicians and by various plans of treatment. Such a large number of cases, treated under precisely the same conditions, offer peculiar advantages for determining the relative value of the different plans of medication. As a result of the analysis, it appears that those patients taking salicylates lose their pains more quickly than those who are not taking this remedy. Out of 350 cases collected by Dr. Fagge who were treated with salicylates, 288 lost their pains within the first nine days of treatment. Of a series of 350 cases collected by Dr. Hood, and treated with salicylates, 247 lost their pains in the same time. Of 350 cases not treated with this remedy, only 141 lost their pains within nine days. It appears, however, that relapses among patients taking salicylates are "vastly increased," and that, although "patients soon lose their pains, they are left feeble and exhausted after the use of this remedy."

Not less important than the pains and the duration of the disease is the question of cardiac complication. The results of the treatment of 1200 cases are given. In the words of the report: "We find that among the 350 patients treated by the salicylates, 241 suffered from heart affection of some kind or other; among the 350 treated without the salicylates, 227 suffered from this complication; of the 500 without salicylates, 273 were affected. The proportion between the two classes is much the same, but what little advantage there is does not lie on the side of the salicylic treatment."

These facts are at variance with the statements of Maclagan, who maintains that the salicyl compounds destroy the *materies morbi* of rheumatism, and thus prevent the cardiac complications.

CONSULTATIONS WITH HOMŒOPATHIC PRACTITIONERS.

AT the last meeting of the British Medical Association, at Ryde, England, in the surgical address by Mr. Jonathan Hutchinson, and in the medical address by Dr. Bristowe, there were scarcely concealed suggestions of the advisability of yielding the position of the medical profession on the matter of consulting with homœopathic practitioners. The effort, although not a concerted one, excited quite a storm of indignation throughout England. It is evident that some of the London consultants would gladly take in the guineas which might come to them by such consultations. The death-blow to such aspirations, and to some other questionable professional practices, has just been given by a resolution passed by the Royal College of Physicians, in which the fellows, members, and licentiates, are informed that they are expected to uphold their principles by discountenancing all those who "trade" on some "special designation." A similar disposition to countenance irregular modes of practice has been observed in some prominent localities on this side of the Atlantic, but the heresy has not, however, gained many advocates in the regular medical profession of this country.

NOCTURNAL INCONTINENCE OF URINE IN CHILDREN.

FEW practitioners escape the care of frequent cases of children's nocturnal incontinence. It is one of the least dangerous, but at the same time one of the most annoying and persistent disorders of childhood, and any help we may get of a practical sort, especially in the way of prevention, will be welcome to our readers. A recent paper read before the Harveian Society, by Dr. Tom Robinson, has two homely hints that are of value, and to which we desire to call attention. "There is no doubt," he says, "that nurses and mothers are frequently to blame for this troublesome vice. Young children ought to be taken out of bed during the night and placed on a chamber, so as to excite their bladders to act." And again, "Fear will frequently prevent young people from rising in the dark to relieve themselves." If we instruct our patients to take up their children when they go to bed themselves, we shall do much, even in quite young children, to arrest the natural

incontinence of infancy. And no parent should allow children to sleep without a dim but sufficient light, not only that they may readily find the chamber, or the water-closet, but that in case of fire or sudden illness darkness may not add its unknown terrors as a hindrance to their seeking aid, or the means of escape. If they sleep at a distance, or in different stories, the halls also should be lighted.

INJURY TO THE EYES CAUSED BY THE ELECTRIC LIGHT.

As evil effects have followed protracted exposure of the eyes to the electric light, this fact should be known to our readers. Dr. Nodier, of Paris, relates that two officers of the French Navy, engaged about the light on a vessel, were compelled to have their eyes turned on the electric arc for two hours, and suffered in consequence serious visual disorders—conjunctivitis, iritis, and retinitis. It seems necessary for those who are compelled to keep their eyes on the point of light, to protect them by colored glasses. A yellow tint, experience has shown, is better than blue or black, for the reason that yellow arrests more perfectly the chemical rays—the violet and beyond.

On the other hand, it is asserted that the electric light is not only free from injurious effect, but it actually prevents the evil results produced by exerting the visual power in an uncertain light. Both propositions are, probably, true; the eyes are injured by keeping them on the electric arc, but benefited by the superior illumination of dark places or objects.

"MATRICULANT."

WE notice in some of our exchanges, and especially in the announcements of some of the medical colleges, the use of the word "matriculant." As the season is upon us for such annual lists, no better time, perhaps, can be found than the present to call attention to the fact that there is no such word in the English language. The proper word is "matriculate," and is derived from the Latin "*matricula*," a register or roll. There is no such verb as *matriculo*, and, therefore, no participial noun as "matriculant."

THE EYE REFLEXES IN ANÆSTHESIA FROM CHLOROFORM.

IT has long been known that the abolition of the conjunctival reflex is a proof of complete insensibility during the inhalation of anæsthetics. M. Berger proposes to utilize this fact in the course of chloroform inhalations, for determining the necessity for giving or withholding the anæsthetic. The first sign indicating the return out of insensibility after the abolition of the conjunctival or corneal reflex, is a fibrillary contraction of the orbicular muscle of the lower lid, which appears on touching the cornea or conjunctiva.

REVIEWS.

THE PREVENTION OF STRICTURE AND OF PROSTATIC OBSTRUCTION. By REGINALD HARRISON, F.R.C.S. 8vo. pp. 28. London: J. & A. Churchill, 1881.

In this little brochure Mr. Harrison reproduces a paper on the *Prevention of Stricture*, which originally appeared in the *Lancet* of May 15, 1880, and couples with it an article on the *Prevention of Prostatic Obstruction*. In reference to the former subject he claims that a large majority of strictures, excepting those caused by injuries to the urethra, are preceded by more or less chronic gonorrhœa or gleet, and that the most frequent seat of gleet corresponds with that of stricture, namely, the subpubic or deeper portion of the urethra. Holding that gleet is an evidence that stricture will form and not that it has already formed, he deprecates the violent, and especially the instrumental, treatment frequently employed, and attributes those cases of persistent and obstinate urethral discharge, which every surgeon continually meets, to the imperfect means hitherto adopted for dealing with the bulbous and membranous portions of chronically-inflamed urethræ. He then describes an apparatus, which he says he has employed in such cases with much benefit, and which consists essentially of a soft catheter and a small Higginson's syringe, by means of which he "douches" or "irrigates" the urethra with medicated solutions. He claims that in this manner chronic urethral discharges are most readily cured, and that thereby stricture is in many cases prevented.

As regards the treatment of prostatic obstruction, he asserts that catheterism should be commenced upon the first indication of the prostate enlarging, and should be employed daily, or even oftener, with a view of keeping open a direct channel to the bladder, or, as he expresses it, of "moulding" the growth so as to prevent interference with the mechanism of micturition.

He gives one case in which—the patient dying from other causes—a post-mortem disclosed the fact that the enlarged middle lobe of the prostate had been grooved or almost bisected, apparently by persistent catheterism.

These views as to the effects of treatment require much stronger confirmatory evidence than is here given before they can be adopted or even be seriously considered by the majority of the profession.

AIDS TO RATIONAL THERAPEUTICS. By J. MILNER FOTHERGILL, M.D., M.R.C.P. 16mo, pp. 121. New York: G. P. Putnam's Sons, 1882.

In the words of the preface, this work is intended to be useful to the student when first called upon to prescribe for patients. It is one of the "Students' Aid Series." These primers are supposed to facilitate the progress of the student; but it may be well questioned if they do not obstruct rather than aid. The present one supposes some considerable acquaintance with the subject of therapeutics, and officiously offers help to those who do not need it. The kind of help is more than questionable; it is scant, superficial, dogmatic, the principles of doubtful authority, and the pharmacology mixed and inconsequential.

The prescriptions are bulky, disagreeable, and complex. The author delights it in polypharmacy. Forgetting that there is usually one central point of disturbance, he seeks by a multiplicity of agents to oppose various symptoms. For example, in debility, he recommends: ℞. Tinct. digitalis, ♏x.; tinct. ferri mur., ♏x.; sp. chloroformi, ♏xx.; inf. quassiæ, ℥i.—Ter in

die. It is difficult to conceive of a more disagreeable mixture, and this quantity, more than two tablespoonfuls, to be given three times a day. Here is another prescription to promote digestion: ℞. Sod. sulphat., ℥ss.; acid. n. mur. dil., ♏vj.; inf. gent., ℥i. This is also to be given before each meal. The following is a tonic pill: ℞. Strychniæ, gr. i.; fer. sulph. exsic., ℥ss.; pulv. pip. nig., ℥i.; pil. al. et myrrh, ℥ij.—Mft. in pil. 36 div. He recommends iron with a mineral purgative, thus: ℞. Mag. sulph, ℈j.; cit. fer. et quiniæ, gr. v.; inf. quassiæ, ℥j.—Ter in die. In "elderly persons something of this kind is to be preferred:" ℞. Amm. carb., gr. iv.; sp. chloroform, ♏xx.; tinct. nuc. vom., ♏x.; inf. cascarillæ, ℥j.—Ter in die. In "chronic dilatation of the heart," he gives the following pill: ℞. Strychniæ, gr. ij.; pulv. digital., ℥ss.; fer. sulph. exsic., ℥ss.; pulv. pip. nig., ℥j.; pil. al. et myrrh, ℥ss.—M. ft. in pil. 60 div.; 1 bis in die. In this pill the patient receives $\frac{1}{15}$-gr. of the alkaloid, strychnia, daily.

The primer is full of these specimens. Those given are quoted literally, the abbreviations being those of the author. In a small space is crowded much ill-directed and unwise pharmacology. The evil done is remote as well as direct. Students fancy they have in such a work the whole science and art of therapeutics, and are delighted with the ease with which diseases are treated. Why labor over ponderous tomes, when, in the delightful pages of Fothergill, the whole matter is comprehended in the dimensions of a primer.

COMMON MIND TROUBLES. By J. MORTIMER-GRANVILLE, M.D., M.R.C.S. Edited, with additions, by an American physician. 12mo, pp. 185. Philadelphia: D. G. Brinton, 1880.

This little work consists of two parts. Part I. treats of "Common Mind Troubles," in chapters devoted to "Failings," "Defects of Memory," "Confusions of Thought," "Hesitation and Errors of Speech," "Low Spirits," "Tempers—Good and Bad," and "Creatures of Circumstances." To these the American editor adds papers on "Mental Languor and Listlessness," and "Morbid Fear." The editor has so successfully imitated the graceful and flowing style of the author, that his contributions read like those of the original work.

In the second part, under the general title—"The Secret of a Clear Head," are papers on "Temperature," "Habit," "Time," "Pleasure," "Self-importance," "Consistency," "Simplicity," and "The Secret of a Clear Head." The editor has made no additions to this part of the work. Some of the essays are concerned with the highest questions of morals, of mental physiology and hygiene, and of sociology, but they are discussed in a lucid, familiar, but dignified style, and may be read with profit by physicians, although intended for general readers. The book is cheaply constructed, the type worn, the paper inferior, but it is nevertheless legible.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 19, 1882.

FORDYCE BARKER, M.D., PRESIDENT, IN THE CHAIR.

After various reports by officers of the Academy had been made and acted upon, the President introduced Dr. S. W. GROSS, of Philadelphia, who proceeded to read the paper of the evening, entitled:

The Influence of Operations upon the Prolongation of Life and Permanent Recovery in Carcinoma of the Breast. (See MEDICAL NEWS, January 21, 1882, page 64.)

Dr. GEO. A. PETERS being called upon by the chair to open the discussion, remarked, that when he began his surgical practice, which now dated back more than thirty years, he was taught that it was hardly worth while to meddle with carcinoma of the breast, for it was sure to return, and that operation rather hastened than retarded death. He had early failed to see the force of that teaching; he had operated many times, and his experience had been much the same as that of Dr. Gross. He could recall at the present time, three cases of successful operation. One was that of a lady between forty-five and fifty years of age, upon whom he had operated for carcinoma some sixteen or eighteen years ago. She was still alive and free from any recurrence of the disease. He had operated as Dr. Gross recommended, removing with the tumor the covering of the pectoral muscle as well as dissecting away some portion of the muscle. The axilla was also opened, and infected glands removed. The second case was that of a young woman, thirty years of age, from whom he removed the entire gland more than ten years ago. The axilla was not opened, as there were no evidences of its contamination. The patient was still alive and enjoyed good health. In the third case, operated on more than ten years ago, the axilla was opened and contaminated glands removed. The covering of the pectoral muscle was also dissected off. The patient was still enjoying good health.

Dr. ROBERT F. WEIR was next called upon by the chair, and responded by saying that he had been much impressed with the great mortality (over 17 per cent.) as recorded by the author of the paper. This was much greater than was common in New York. He had operated some sixty or seventy times, and had had only one death, which was due to erysipelas. Since the advent of Listerism in 1875, we operated more boldly, and, as a result, our patients had fewer relapses than in previous times. He thought operation was to be advocated more as a means of prolonging life than as a means of permanent cure. He cited cases to show that patients might be free from the disease for sixteen or seventeen years, or even more, after which the disease would recur.

Dr. THOMAS E. SATTERTHWAITE remarked that during the past ten years he had collected a number of cases of carcinoma, and had been to some pains to have those patients, still struggling along, called upon at their homes and examined. In June last he had collected 36 cases, many of them being known to physicians present. Of the three forms of cancer of the breast—scirrhous, encephaloid, and colloid—80 per cent. of the cases collected by him were scirrhous. Traumatism, as a cause, was associated in about a third of the cases. About one-half of these, or one-sixth of the whole number, had a hereditary taint of cancer. In New York, the deaths from operation did not amount to 3 per cent., between the time of operation and the eighth day. Of 31 cases of which he had complete records, and had himself made the microscopical examinations, 3 might be classed as cured, which gave a percentage of 10. In these cases there had been immunity from disease, six, seven, and ten years, respectively. In reference to the question as to whether early operation secured better results, he had twice attempted its solution, but was still in doubt. In two of the three cases of cure above alluded to, the operation was done early, four and six months, respectively; but in the third case the operation was performed after an interval of five years. An explanation might be found in the view that in cases where long intervals elapsed before operation, the tumor remained benign for several, or many years and then became malignant.

The PRESIDENT said that some ten or more years ago, when the senior ex-president of the Academy, Dr.

Willard Parker, read a very interesting paper on this subject, he (Dr. Barker) had called attention to an observation he had made, viz., the older the patient at the time of the operation, the less likely or less early would be the disease to return, and *vice versa*.

Dr. LEWIS A. SAYRE remarked that he had been taught, as Dr. Peters had been, that when cancer of the breast was diagnosticated, to let it alone. That operation hastened the death of the patient. That operation was to cancer what hoeing was to a hill of corn; the more it was hoed the better it grew. For twenty or thirty years he had been in the habit of removing all cancerous breasts that came under his treatment, that were not so far advanced as to preclude operation. Since Dr. Atlee, in a paper read before the American Medical Association, about the year 1847, had detailed the beneficial results derived from the internal administrations of arsenic in cancer, it had been his custom to give it in all cases, and he must say the results had been gratifying. Some of his patients operated on over twenty years ago were still alive and in good health.

Dr. FRANK HASTINGS HAMILTON said he regarded the pivotal point of this discussion to be, whether the disease was primarily a local, or a constitutional malady. He had observed that cancer of the breast occurred at a time of life when that organ was going into decay, and especially in those who had never borne children. In this fact there was no evidence of constitutional fault, as all other parts of the body were in good condition. We all know how epithelioma might arise from traumatisms, or long-continued local irritation. In the history of such cases there was a time when the disease was purely local.

Dr. ALFRED C. POST had always been in favor of the removal of cancers of the breast, and his practice had been in accordance with this view. His results had been very satisfactory on the whole. The fact to which the President had called attention he had long observed.

Dr. WILLARD PARKER said he had collected the histories of between four and five hundred cases of cancer of the breast which had come under his own observation, either as patients or in consultation. When he undertook the review of these histories he was of the opinion and taught that cancer of the breast was of hereditary origin. As a result of his tabulations he came upon the conclusion unequivocally that it was not hereditary. He believed traumatism to be the exciting cause in most cases.

Dr. AUSTIN FLINT, Sr., moved that a vote of thanks be tendered to Dr. GROSS by the Academy of Medicine for his valuable paper, which was adopted, and the Academy then adjourned.

MICHIGAN STATE BOARD OF HEALTH.

Stated Quarterly Meeting, January 10, 1882.

The regular quarterly meeting of this Board was held January 10, 1882, in Lansing, the full Board being present.

The SECRETARY presented his quarterly report, showing some of the work in the office during the past quarter. The quarter had been a very busy one, made so, in part, by the numerous outbreaks of diphtheria, scarlet fever, and small-pox in the State, which had required much correspondence and the sending out of many documents. The compilation and issuing of the weekly bulletin of health in the State is now so systematized as not to take as much time as at first. It is published in probably two hundred newspapers in Michigan. In response to a request, fifty-seven health officers of villages have begun to make weekly reports of disease. The Board reaffirmed the demand for these reports from health officers of cities. To each place in the State where diphtheria, scarlet fever, or small-pox was reported present, a letter was written to the health authorities giving full instructions and suggestions how to prevent the spread of the disease. Documents containing elaborate and particular directions have been sent for free distribution throughout the vicinity. Each officer was requested to make a special report on the epidemic under his care, and some of the reports show how, by determined action, to stamp out a contagious disease. As showing the necessity for inspection and disinfection of immigrants, their clothing, baggage, etc., and especially for a system of surveillance to their destinations, a statement was made by the Secretary of the introduction of typhus fever in Benzie County, by Norwegian immigrants. The disease made its appearance over sixty days after the arrival of the immigrants, and spread quite freely (not being reported at the time or treated as a contagious disease by the local authorities), causing many cases of illness, and at least three deaths. The importance of inspection of immigrants at Port Huron, and of keeping those believed to be liable to spread communicable diseases under surveillance until their destination is reached, and then placing them in the watchful care of the local Board of Health, was freely discussed. As this Board has no funds available for such a purpose, the subject was referred to the President, Secretary, and Dr. Lyster, to confer with the National Board of Health, and take such action as is possible.

A report by the Hon. LE ROY PARKER, relative to duties of health officers in verifying diagnoses of contagious diseases, was read and ordered printed in the Annual Report. Mr. Parker reported the following: In Gaines Township, Genessee County, a child of Mr. B——s died of what the doctor called malarial fever, and did not report the case to the board of health, though it seems probable that it was really diphtheria. A neighbor and wife, Mr. and Mrs. B., assisted in preparing the corpse for burial. About the same time a child of Mr. S. died from "sore throat," not reported as "dangerous to the public health," and some of the children of Mr. B. attended the funeral. Soon after, Mrs. B. was taken sick with diphtheria, and in turn 13 out of 14 members of the family had it, and 7 out of 10 children died. The Board of Health promptly isolated this household, but the attending physician's error in diagnosis, or failure to report the first case, was fatal to the hopes of that family. In this connection the Board adopted the following preamble and resolutions:

Whereas, It is often difficult to recognize mild cases of diphtheria, or to distinguish such cases from a simple pharyngitis or laryngitis, and

Whereas, Such mild cases of diphtheria often communicate a dangerous and fatal form of diphtheria,

Resolved, That it is the duty of physicians and householders in reporting diseases dangerous to the public health, and of local health authorities in their efforts to restrict such diseases, in every case to give the public safety the benefit of the doubt.

Resolved, That suspected cases of dangerous diseases should be reported, and precautionary measures should be taken.

Drs. Kellogg and Avery were appointed a special committee to report on the present knowledge of diphtheria, and Dr. Lyster was appointed a special committee to report upon the present knowledge of typhoid fever.

Mr. PARKER reported that persons guilty of removing contagious-disease placards from their houses, could be punished under the law, which made the house in which the contagious disease was, a hospital, if declared so by the Board of Health, and subject to their rules and regulations. All rules and regulations of a Board must

first be published, then penalties may be inflicted for any violations.

Dr. AVERY, as special committee on the subject, made a report relative to the overflowed lands in Gratiot and Clinton Counties, and presented a resolution from the Board of Supervisors of Gratiot County. In accordance with the report, the Board adopted a preamble and resolution as follows:

Whereas, The Board of Supervisors of Gratiot County has passed resolutions asking this State Board of Health to investigate the subject of the sickness caused by the overflow of Maple River, because of the dam at Maple Rapids, and "to advise the removal of said dam as being detrimental to the health of the communities living in the vicinity of said river," therefore,

Resolved, That the Board of Supervisors of Gratiot County be informed that this Board has already had an investigation made, and from the report of such investigation, is convinced that the dam at Maple Rapids causes a nuisance, and advises that in case the owner of said dam will not remove the same, and thus abate the nuisance caused by the overflowing of land along said river, a bill in equity should be filed against the owner of said dam, to compel him to remove the same.

The Secretary was directed to correspond with persons in some cities in the western part of the State, relative to holding a second Sanitary Convention this winter. One will be held at Ann Arbor, February 28, and March 1. These conventions are held in accordance with invitations received from citizens, and under arrangements made by a local committee acting with a committee of this Board.

Dr. HAZLEWOOD reported on the inspection of summer-resort hotels as regards danger from fire, and asked if the present law providing for such inspection was not sufficient. Dr. Baker thought the law should be amended so as to take the inspection duties away from the political officers, and place them among the duties of Local Boards of Health. The question was referred to Mr. Parker, committee on legislation, in the interest of health.

The SECRETARY presented a report of work of local boards of health, showing much good work done during the past season in the restriction of contagious diseases. He read letters showing the action of local boards of health with contagious diseases: one from J. R. Thomas, M.D., Health Officer of Bay City, relative to diphtheria; one from W. G. Elliott, M.D., Health Officer of Pontiac, relative to scarlet fever; and one from Foster Pratt, M.D., Health Officer of Kalamazoo, relative to small-pox.

The SECRETARY also read a résumé of work of other State Boards of Health, and it showed that typhoid fever was very widely prevalent; that small-pox was very prevalent in the northern and northwestern States, and that intermittent fever was present in Connecticut, Massachusetts, and Rhode Island.

The next regular quarterly meeting of the Board will be held April 11, 1882. There will probably be a special meeting of the Board in connection with the Sanitary Convention at Ann Arbor, Feruary 28, and March 1, 1882.

CORRESPONDENCE.

HYPERMETROPIA IN THE PUBLIC-SCHOOL CHILDREN.

To the Editor of THE MEDICAL NEWS:

SIR: Will you kindly allow me to corect an error through your columns on a subject which is of interest to many besides myself, and which, if uncorrected, might lead to an erroneous impression. In the report on *Weak Eyes in the Public Schools of Philadelphia*, just published, Dr. S. D. Risley observes: "In the statistics compiled by Drs. Loring and Derby, of New York City, there was but twenty-seven per cent. of myopia in the highest class. Another marked difference is shown in comparing their tables with those of European observers. All the foreign statistics, except those of Conrad, show, expressed in general terms, a low percentage of emmetropic eyes, and a high percentage of hypermetropia." (p. 11.)

That "*all foreign* statistics, except those of Conrad," do not "show a high percentage of hypermetropia" will be seen from the following list, which a cursory glance over the literature has produced, and which I have no doubt could be extended if there was any occasion for it. The list gives the percentage of hypermetropia found by fifteen foreign observers:

	Per Cent.
Jaeger,	7.6
Cohn,	2.3
Thilenius,	2.9
Erismann,	43.3
Malakoff,	3.0
Cohn,	7.0
Krüger,	17.7
Hoffmann,	26.6
Reuss,	20.5
Ritzmann,	5.7
Gayat,	6.8
Dor,	4.18
Conrad,	11.76
Pflüger,	44.
Becker,	12.

The percentage obtained by Dr. Derby and myself was 13.00 per cent. Out of the above fifteen observers ten get a lower. If we take the average of all the above observers, high and low, it amounts to but 14 per cent. Dr. Risley obtained 74 per cent.

So much for foreign statistics. Not only do the statistics published by Dr. Derby and myself agree in a marked manner with the average of the above European observers in regard to hypermetropia, but they also agree in an equally marked manner with that of the predecessors of Dr. Risley in this line of investigation in this country, to which he alludes in an incidental sort of a way as the "work of several Americans," these being Drs. Williams, Ayres, Webster, Cheatam, Agnew, Matthewson, Prout, Mittendorf, and others.

That the public schools of Philadelphia should contain *six times* as much hypermetropia as do the schools of New York, as determined by half a dozen different examiners at different periods is certainly a curious fact, if it be one, and all the more curious as the same methods were adopted, and the same precautions taken in the compilation made by Dr. Derby and myself, as in that made by Dr. Risley.

Respectfully yours,
EDWARD G. LORING, M.D.

NEW YORK, January 19, 1882.

NEWS ITEMS.

NEW YORK.

(*From our Special Correspondent.*)

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—An interesting paper was read at the December meeting of this Society by Dr. H. H. Kane, of this city, upon the use of opium as a remedial agent. The early part of his paper was devoted to a sketch of the use of opium as a stimulant by presumably healthy persons, and to illustrate the usual manner of using it, a complete opium-smoking bunk, smokers included, was introduced. While admitting the capacity of the drug

to work mischief, the reader believed that the effects of opium smoking were greatly exaggerated, and by contrast with the effects of alcohol, were, comparatively speaking, slight.

As a remedial agent, notably in cases of tuberculosis and other wasting diseases, the results seemed to be merely temporary, the progress of the disease being checked during the administration of the drug, to resume its activity when the use of the opium was abandoned. Hence its action seemed to be rather in the direction of checking metamorphosis of tissue than that of a true curative agent.

A NEW MEDICAL PUBLICATION.—It is said that a new journal, the first number of which will be issued in February, is to be published in this city, which, if carried out as proposed, cannot fail to be of great interest to the medical public. Its title is the *Illustrated Quarterly of Medicine and Surgery*, and its publisher is E. B. Treat, the same who brought out Dr. Fox's admirable *Photographic Illustrations of Skin Diseases and Cutaneous Syphilis*. Four numbers will be issued during the year, each number to consist of four plates, chromolithographs, autotypes, or fine wood-cuts, illustrative of various diseases in medicine, surgery, and pathological anatomy. Accompanying each plate will be the history of the case depicted, besides short practical articles, illustrated by wood-cuts in the text, from the pens of eminent men in the profession. The editors are two physicians, who are connected as teachers with two prominent New York medical schools.

ENFORCEMENT OF THE MEDICAL LAW.—This work still goes on actively, the Medical Society of the County seeming to be as diligent as ever in the pursuit of "irregular practitioners." One hopeful feature, is that most of them after being prosecuted once, do not feel disposed to try it over, although here and there cases occur, but the censors of the Society watch such persons closely, and rearrest them as soon as sufficient evidence can be obtained. One such case is already on trial, the man Cox (alluded to in a former communication), has been caught illegally practising a second time, notwithstanding his former conviction. The penalty for subsequent offences, the law declares, shall be "a fine of not less than one hundred dollars, nor more than five hundred dollars, or by imprisonment for not less than thirty nor more than ninety days, or both;" and this latter sentence, "or both," *i. e.*, fine and imprisonment, the censors mean to try to secure.

Another salutary feature, in the opinion of the County Society, is the necessity of endorsing diplomas which are issued outside of the State, and this section of the Pennsylvania law, which is objected to by the Philadelphia medical schools, on the ground that "they regard it as offensive and unjust for the faculty of a medical school in this State to sit in judgment on the qualifications of a medical man, attested by the signatures of a faculty in good standing in another State," is here thought to be a wise and good provision.

EDINBURGH.

(*From our Special Correspondent.*)

EDINBURGH UNIVERSITY.—The large number of medical students during the present session is without parallel in the history of the university. In the year 1880 there were 1638 matriculations, or an increase of about 50 over the previous year, or, comparing it with the year 1875, an increase of more than 700. Probably, in no other medical school in the world has so large an attendance ever been recorded. The wide area from which the students are drawn, is also remarkable. During last year Scotland contributed 638, or about 38 per cent.; England, 585, or 35.7 per cent.; Ireland, 30, or 1.8 per cent.; India, 120, or 7.3 per cent.; the colonies, 202, or 12.3 per cent.; and foreign countries, 63, or 3.8 per cent. The number of those who graduated is not so large as might have been anticipated from the number of students; only 35 took the degree of Doctor of Medicine (M.D.), and 133 the double degree of Bachelor of Medicine and Master in Surgery (M.B.C.M.), 4 taking the degree of Bachelor of Medicine (M.B.) alone.

EDINBURGH UNIVERSITY, CHAIR OF NATURAL HISTORY.—This chair, owing to the resignation of Sir Wyville Thomson, who is well known as the leader of the scientific expedition with H.M.S. "Challenger," is at present vacant. Sir Wyville suffered nearly two years ago from an attack of apoplexy, and, although he has sufficiently recovered to be able to superintend the investigations and publications which the voyage of the "Challenger" has entailed, he has not found himself equal to the discharge of his duties as professor of natural history in the university. The emoluments of the chair, which are mainly derived from students' fees, amount to little less than £2500 per annum, and thus constitute it much the wealthiest zoological appointment in Britain. The selection of a successor to Sir Wyville rests with the Crown, and it is understood that the chair has been practically offered to Prof. Huxley, of London, and afterwards to Dr. F. M. Balfour, Fellow of Cambridge University, whose excellent work on *Comparative Embryology* is recognized as the best contribution of recent years to the intricate subject of development. Both, it is stated, have declined to vacate their present posts. The candidates announced are Prof. Young, of Glasgow; Prof. Alleyne Nicholson, of St. Andrews; Prof. Cossar Ewart, of Aberdeen; Prof. Ray Lankester, of University College, London; Prof. Cunningham, of Belfast; Dr. Mackintosh, superintendent of Perth District Asylum and examiner in natural history in the university; and Mr. Geddes, lecturer on zoology in the Edinburgh extramural school. There is, therefore, no lack of able men, and it is to be hoped that the fittest will be chosen. The appointment, it is expected, will be made very soon.

PHILADELPHIA COUNTY MEDICAL SOCIETY.—At the annual meeting, held January 18, the following officers were elected to serve during the ensuing year: President, H. Y. Evans; Vice-Presidents, C. K. Mills, John B. Roberts; Recording Secretary, Henry Leffmann; Reporting Secretary, Frank Woodbury; Corresponding Secretary, H. Augustus Wilson; Assistant Secretary, J. D. Nash; Treasurer, Wm. M. Welch; Librarian, M. O'Hara.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.—At the annual meeting, the following office bearers were elected for the ensuing year: President, S. W. Gross; Vice-Presidents, Jas. Tyson, J. Solis Cohen, F. P. Henry, J. Ewing Mears; Secretary, S. F. Hazelhurst; Treasurer, M. S. French; Recorder, Chas. B. Nancrede; Curator, Carl Seiler.

BALTIMORE MEDICAL ASSOCIATION.—At the annual meeting of this Society, held on the 9th inst., the following officers were elected for the year 1882: President, Dr. Christopher Johnston; Vice-Presidents, Drs. W. F. A. Kemp and T. A. Ashby; Recording Secretary, Dr. Eugene F. Cordell.

HARVARD UNIVERSITY MEDICAL SCHOOL.—The cost of the new building now being erected at the corner of Boylston and Exeter Streets, Boston, for the use of the Medical department, will not be less than $190,000. $83,325 having been expended for the site, there remains

of the money collected for the building about $190,000. Work was begun upon the building early in June last, and it is hoped that the whole building will be ready for occupation by the 1st of January, 1883.

Two scholarships, one of the annual value of $300, and one of $200, will be established in the Medical School, from a part of the bequest of the late Edward M. Barringer, of Schenectady. These scholarships are the first which have been endowed in the Medical School.

The whole number of students in attendance during the year was 251; of these 120 had a literary or scientific degree. There were 85 applicants for the degree of Doctor of Medicine, of whom 25 were rejected.

The fourth year course was composed of a class of 10 students, of whom 5 received hospital appointments, one the ordinary degree of M.D., and four applied for the special degree; but as none of them fulfilled all the requirements, this degree was not awarded.

Nine volumes were added to the Medical Library, making the total number of volumes 2009.

SAN FRANCISCO COUNTY MEDICAL SOCIETY.—At the annual meeting of this Society the following officers were elected to serve during the year 1882. President, Dr. Wm. H. Mays; Vice-Presidents, J. D. Wilson, M.D., and C. E. Blake, M.D., and Recording Secretary, W. H. A. Hodgdon, M.D.

THE SOCIETY OF PHYSICIANS AND SURGEONS OF ALAMEDA COUNTY was organized last October. Prof. S. H. Wythe was chosen President, and Dr. E. S. Barber Recording Secretary. The regular meetings will be held on the first and third Thursdays of every month; at the first meeting of every month papers will be read on some subject pertaining to medicine or surgery, and the second meeting will be devoted to reports of cases and discussions.

A SANITARY CONVENTION, under the auspices of the State Board of Health, will be held on February 28 and March 1 at Ann Arbor, Mich. Manufacturers of, and dealers in, all kinds of sanitary apparatus or appliances are invited to send specimens of their articles for exhibition at the Convention, and certificates of merit will be awarded to such articles as are deemed worthy.

Among the subjects to be presented and discussed are the following: (1) Ventilation; (2) Causes of Insanity; (3) Injuries to Health from Overflowed Lands and from Mill-dams and other Obstructions in Rivers; (4) Water Supply and Disposal of Waste Matter; (5) School Life and Hygiene.

HEALTH IN MICHIGAN.—The weekly Board of Health bulletin states that inflammation of bowels, typhoid fever, pneumonia, diphtheria, cerebro-spinal meningitis, erysipelas, measles, and small-pox increased considerably, and influenza and remittent fever have decreased considerably in area of prevalence.

Small-pox was reported at Bay City, Detroit, Grand Rapids, Marcellus (Cass County), and South Haven. New cases were reported at Grand Rapids, January 15. These five places were reported as having 19 cases from January 7 to January 15.

An epidemic of measles is reported at Albion, Jan. 17.

SMALL-POX.—We learn that during last week there were at New York thirty-nine cases of small-pox, and seven deaths, and at Brooklyn, thirteen. In Hudson County, New Jersey, the disease is thought to be abating, while at Hoboken it is on the increase. At Port Jervis the Board of Health has not succeeded in suppressing the disease; about sixty cases in all have been reported, with seven deaths. At Philadelphia there were twenty-three deaths; Pittsburg, twenty deaths; and at Allegheny nineteen deaths. At Pittsburg fifty-six, and at Allegheny twenty-seven new cases were reported from January 21 to 23. There were reported to the National Board of Health, for the week ending January 21, at Boston, one new case and one death; at New Haven, four new cases; at Wilmington, Del., one death; at Cleveland, Ohio, one death; at East Liverpool, Ohio, twelve new cases; at Dayton, four new cases and one death; at Louisville, four new cases and one death; at St. Louis, fifteen new cases and two deaths; at Richmond, thirty-five new cases and two deaths; at Galveston, seven new cases.

THE PARIS MEDICAL SOCIETIES.—M. Dujardin-Beaumetz has just been elected President of the Société Médical des Hôpitaux; M. Léon Labbé, of the Société de Chirurgie; M. Duroziez, of the Société de Médecine.

DEATH UNDER CHLOROFORM AND ETHER.—The *Lancet* for Dec. 31, 1881, states that a patient in the week before died at the Great Northern Hospital whilst under the influence of a mixture of chloroform and ether, administered preparatory to the removal of the nail of the great toe. The anæsthetic was given on lint, and the operation was completed, when it was discovered that the pulse had ceased, and the patient succumbed in spite of every effort adopted to restore animation.

MEDICINE IN JAPAN.—According to the *Lancet*, December 24, 1881, Japan possesses 159 hospitals, in which the patients are treated on principles recognized by Western nations. Vaccination is performed gratuitously, and is compulsory. Moreover, a sort of Medical Act has been lately passed, by which persons without certificates are prohibited from practising medicine or surgery.

EXECUTION OF CRIMINALS BY ELECTRICITY.—A German exchange suggests the following method of procedure for the execution of criminals by electricity. In a dark chamber hung with black, and lighted by a single torch, there is a statue of Justice, with the balance and sword, and a seat, on which the criminal is fastened, connected with a powerful battery in the statue. No one is to be present but the judge, the jury, and necessary officers. The ceremony commences with the reading of the sentence; this terminated, the judge breaks his bâton and throws it on the scale of the balance, at the same time extinguishing the torch. The scale descends, the circuit is closed, and the criminal thrown into the other world.—*Journ. de Méd. de Paris*, Nov. 26, 1881.

The feasibility of the method has unfortunately been already unintentionally illustrated with the electric-light apparatus. The *British Medical Journal* for December 24, 1881, relates the death, in England, of a laborer, who received a fatal shock from accidentally touching an uninsulated wire which was conducting the current for sixteen Brush lights. A number of serious accidents have also been caused in this country from defective insulation, and we believe, in at least one instance, a fatal result (in Pittsburg) has followed.

RUPTURE OF THE BLADDER.—In the *Lancet* for Dec. 10, 1881, Dr. J. T. Call publishes an account of a remarkable case of rupture of the bladder into the rectum, with no consequent infiltration of the cellular tissue with urine, and in which recovery occurred spontaneously.

DANGER IN ETHER INHALATION.—In the *Nashville Journal of Medicine and Surgery* (Dec. 1880), an accident, which narrowly escaped being very serious, is re-

ported to have occurred while anæsthetizing a patient with ether. A tumor was being removed from the parotid region under carbolic spray, when the flame of the spirit-lamp of the atomizer communicated with the ether and the vapor and clothing of the patient instantly caught fire. Fortunately, the flames were extinguished before any injury was inflicted.

POISONING BY WINSLOW'S SOOTHING SYRUP.—In the *Sanitary News*, December 15, 1881, there is a report of another death of a child eight months old, from the administration of a teaspoonful of "Mrs. Winslow's Soothing Syrup," the symptoms of poisoning by morphia being well marked. Analyses of this dangerous nostrum have shown that each ounce of the syrup contains *one grain* of morphia, so the dose, according to the directions on the bottle, for a child eight months old, contained *one-eighth* of a grain of morphia. It is about time that legal proceedings should prohibit the sale of such dangerous compounds, when advertised as inoffensive.

BACILLUS MALARIÆ.—Dr. C. A. MacMunn states in the *British Medical Journal*, for December 10, 1881, that an examination of a drop of blood taken during a chill, from a patient who had contracted malarial fever in Africa, showed most distinctly the presence of the malarial bacillus.

PASSAGE OF AN ARTIFICIAL TOOTH PLATE.—Dr. Frederick F. Palmer gives an account in the *Lancet* for December 10, 1881, of an instance in which a gold plate with two artificial teeth, and having a sharp projecting hook, was accidentally swallowed, and passed through the alimentary canal without doing any injury, and with an almost entire absence of pain.

EFFECTS OF THE ELECTRIC LIGHT ON THE EYESIGHT.—M. Nodier mentions in the *Revue Scientifique*, December 10, 1881, the instance of two naval officers, who, after some experiments with the electric light, were attacked with quite serious visual troubles; there was marked photophobia, slight conjunctivitis, lacrymation, contraction of the iris, and flying spots in the eyes.

THE MAN WITH THE ELASTIC SKIN.—The *Wiener Med. Wochenschrift* states that a man is now exhibiting in that city a peculiarity highly interesting to medical men. This consists in an enormous and astonishing elasticity of his skin. He is able to raise this in folds from his trunk or limbs to the extent of more than a foot; and as soon as the traction ceases the skin resumes its normal position, neither folds nor depressions being visible. The procedure is entirely painless. When the skin is touched it imparts a sensation as if one had hold of a fine sponge, and as if it were much too large for what it covers. Even the hairy scalp and the skin of the nose and palm of the hand exhibit the peculiarity, but to a less extent than that of the trunk or arm. So delicate is the skin, and especially of the upper extremities, that when it is raised in a fold and held before a light, it is found to be transparent, exhibiting the course of the vessels. The "India-rubber" man is thirty-two years of age, and the peculiarity was first observed in his twenty-first year.—*Med. Times and Gazette*, Dec. 3, 1881.

DOUBLE MONSTROSITY.—Dr. Joseph Stedman reports an interesting case of a double monster, twins united by the chest and belly (thoracopagus), having a cord carrying two arteries and two veins, the ductus venosus entirely wanting, the auricular portions of the heart united into a common cavity, with no right auriculo-ventricular opening in the case of fœtus B, and in consequence the lungs receiving their blood from the aorta through the ductus Botelli. The livers fused into one mass, with an absence of gall bladders, the duodenum opening freely into the abdominal cavity, and the small intestines recommencing again with two large ampullæ, also opening into the abdominal cavity.—*Boston Med. and Surg. Journ.*, Dec. 22, 1881.

PERSONAL.—The Order of the Cross and Collar of Knight Commander of the Crown of Italy has been conferred upon Sir William Mac Cormac by King Humbert, in recognition of his distinguished scientific attainments.

NOTES AND QUERIES.

IS THE RADESYGE SYPHILIS?

DR. MAGELSSEN, of Rushford, Minn., writes us that the "radesyge" is really syphilis, and that form which the French writers call "syphilide tuberculo—serpigineuse," and the Germans "lupus syphilitica." For further information on the subject he refers to *Recueil d' Observations sur les Maladies de la Peau*, par W. Boeck and D. E. Danielssen, 2d livraison, La Radesyge, Christiania, 1860, and *Recherches sur la Syphilis*, par W. Boeck, Christiania, 1862, p. 681.

"THE FUTURE OF INOCULATION."

Our clever contemporary *Punch*, in a late number, gives, as a practical development of Pasteur's recent researches upon inoculation of cultured disease germs, a well-drawn picture of the interior of an apothecary shop, where the following dialogue is taking place:

Customer.—"My nephew is just starting for Sierra Leone, and I thought I could not make him a more useful present than a dose of your best yellow fever. Would you tell me the price, please?"

Chemist.—"Well, ma'am, the germs are so difficult to cultivate in Europe, that I would advise your waiting for the next West-Indian mail, when I am expecting a nice fresh consignment from St. Thomas. Meanwhile we would recommend our half-guinea traveller's assortment of the six commonest zymotics, and could add most of the tropical diseases from stock at five shillings each. We have some nice Asiatic cholera, just ripe, but they are more expensive."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 17, TO JANUARY 23, 1882.

GARDNER, WM. H., *Captain and Assistant Surgeon.*—Now at St. Augustine, Fla., to proceed to San Antonio, Texas, and report in person to the commanding general, Department of Texas, for assignment to duty.—*S. O. 14, A. G. O., January 19, 1882.*

LA GARDE, L. A., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month, to take effect on arrival of A.-A.-Surgeon Collins at Cantonment, on the North Fork of the Canadian River, Ind. T.—*S. O. 12, Department of the Missouri, January 16, 1882.*

BIRMINGHAM, H. P., *First Lieutenant and Assistant Surgeon.*—Who returned to Ft. Leavenworth, Kans., on 12th instant, from leave of absence, to proceed to Fort Gibson, Ind. T., and report to the commanding officer for duty, relieving A.-A.-Surgeon Collins.—*S. O. 12, c. s., Department of the Missouri.*

MADDOX, THOMAS J. C., *First Lieutenant and Assistant Surgeon.*—Having reported at these Headquarters in compliance with S. O. 2, c. s., A. G. O., will report to the commanding officer, Fort Clark, Texas, for duty.—*S. O. 6, Department of Texas, January 16, 1882.*

WHITEHEAD, W. E., *Captain and Assistant Surgeon.*—Died at Tarrytown, N. Y., on January 15, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

ORIGINAL LECTURES.

CARTWRIGHT LECTURES.

ON THE EXPERIMENTAL METHOD IN MEDICAL SCIENCE.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, January 31, 1882.

BY JOHN C. DALTON, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

LECTURE II.

BUFFON AND BONNET, IN THE EIGHTEENTH CENTURY.

MR. PRESIDENT AND GENTLEMEN: I shall ask your attention in this evening's lecture to two remarkable phases of physiological doctrine which once held a conspicuous place in the world of science, namely, Buffon's theory of Organic Molecules, and Bonnet's theory of the Inclusion of Germs. Notwithstanding that both are now so obsolete that, perhaps, the majority of my hearers will hardly recall their meaning, they were formerly considered of sufficient importance to be test questions in the controversies of the period, and they are fair examples of the fluctuating estimate to which such subjects are liable at different times.

It occasionally happens that, in searching the annals of medicine, we find allusions to systems and theories which have so far gone out of vogue that we know them only by name. They are no longer part of our scientific doctrines; and they have so little present value or significance that we seldom spend the time even to weigh their merits or defects—and yet these systems once had their day. They were prominent topics of discussion and interest; and they divided medical opinion between the views of antagonistic parties, or carried with them the scientific world in a temporary enthusiasm of acceptance and admiration. They were often originated by men of learning and ability, and owed much of their success to the superior talent of their authors. They were usually ambitious in design and seductive to the imagination. They claimed to open a wider field of knowledge, and to unlock the secrets of nature by some new formula that should dispense with the older and slower methods of plodding investigation. So long as they held out this prospect, they stimulated the hopes and attracted the interest of all. But after a time it appeared that the anticipations which they excited were not fulfilled, and that their promised results failed of realization. Then the theories themselves began to lose in importance; and, once started on the downward road, they receded more and more rapidly from view, until they passed out of sight, and out of mind. They vanished into the limbo of departed spirits; and if they ever show themselves at the present day, it is only to gratify a momentary curiosity as the relics of thought and opinion in former times. Like unsubstantial shadows, they flit across the pages of a forgotten literature, and the glimpses that we catch of them, here and there, are the only traces of their existence in the history of the past.

One of these phantoms, alive and flourishing a hundred years ago, was Buffon's theory of *Organic Molecules.*

Buffon was a remarkable instance of a man of splendid but temporary reputation. His ability commanded the attention of his contemporaries, and enlisted their interest and co-operation for natural history, as no modern writer had done before. His immediate successors were fond of comparing him with Aristotle and Pliny; and if we take their estimate of his reputation, there have been few men, either in science or literature, who ever acquired so great a popular renown. He was a member of the French Academy, of the Academy of Sciences, of the Royal Societies of London and Edinburgh, and of the Academies of Berlin and Bologna. He was created a Count by Louis XV., and was for forty years superintendent of the Garden of Plants (then the "Garden of the King"), which he more than doubled in extent, and where his statue was erected while he was yet alive. His great work on natural history was received as an authority from the date of its publication; most of the European potentates sent him specimens for his museum, or complimentary messages; strangers from abroad thought it a privilege to see him; and among the visitors at his country house were Thomas Jefferson and the Prince of Prussia.

Notwithstanding this extraordinary success, Buffon's qualities could not secure a lasting reputation. He excited the enthusiasm of his readers by his eloquence and originality, but he did not give them much real instruction. This deficiency was felt, even by his friends. Viege d' Azyr, who pronounced his eulogy in the French Academy, and who calls him "one of the lights of the age, and an ornament to his country," says that he often "compels admiration, without convincing the judgment." According to Moreau, he "supplemented by the brilliancy of his imagination the imperfections of his knowledge," and showed himself "more remarkable for boldness of conception than for precision of ideas." There can be no doubt that he did much, in his own time, to popularize natural history among the educated and influential classes, but it was rather as an intellectual entertainment than a scientific pursuit; and his works are now nearly destitute of value for any purposes of reference or exact information.

It appears that Buffon's style as a writer was one of his principal charms for the readers of that day, and formed a large element in his success. It had a sort of poetic splendor, that would be thought quite inadmissible at present in a scientific work, and sometimes will hardly bear translation without a close approach to puerility; but at the period when he wrote, and in his hands, it magnified his subject, and made an impression upon his readers. He often adopts this lofty tone at the opening of a chapter, and nearly always employs it for descriptive passages. He introduces the horse as "this proud and impetuous animal, the noblest conquest ever made by man, his companion in the fatigues of war and in the glory of combats." "The elephant," he says, "makes the earth tremble beneath his footstep, uproots trees from the soil, and with one thrust of his body will batter down a wall." Buffon took great pains to cultivate and perfect this style. They say he would often repeat aloud certain passages, or get his friends to do so, with himself for an audience, to enjoy the sound of his swelling sentences, and, perhaps, make some improvement in their construction. One of the extracts which he was especially fond of hearing in this way, was his delineation of the feelings of the first man, when just awakened to consciousness and vitality. The newly created being is supposed to be telling his own story, as follows:[1]

[1] Œuvres Complètes de Buffon. Second Edition. Paris, 1819. Tome x., p. 358.

"I well remember that instant of mingled joy and anxiety when I felt for the first time my extraordinary existence. I knew not what I was, where I was, nor whence I came. I opened my eyes. What an overflow of sensation! The daylight, the celestial vault, the green earth, the crystal transparency of the waters, all attracted me, excited me, and gave me an inexpressible sense of enjoyment." And so on for seven or eight consecutive pages.

Another favorite passage was his picture of an Arabian desert, introduced *apropos* of the natural history of the camel.[1]

"Imagine," he says, "a region without verdure or moisture, a blazing sun, the sky always arid, plains of sand and mountains still more parched, where the eye searches in vain for any trace of a living creature; a land lifeless, and, as it were, stripped by the winds; where nothing is to be seen but dead bones, scattered pebbles, and rocks standing or overturned; a barren desert, where the traveller never finds a shady resting-place, where he has no companionship, nor anything to remind him of life in nature; absolute solitude, a thousand times more frightful than that of the forest, since even trees are living beings for the man who is there alone. In these void and measureless regions, more isolated, denuded, and desolate than any other, the empty space seems to enclose him like a tomb. The light of day, more gloomy than the shades of night, returns only to disclose his impotence and destitution. It shows him the horror of his situation by enlarging before his eyes the boundaries of vacancy, and shuts him out from the habitable world by stretching around him an abyss of immensity which he could never hope to cross."

The satisfaction which Buffon felt in these descriptions does not seem to have been in the least diminished by the fact that he had never seen an Arabian desert, and that his story of the first man was entirely imaginary.

Buffon's *Natural History* was a work of very extensive design. It included an explanation of the structure and physical geography of the globe, the nature of man and animals, a general view of animals, vegetables, and minerals, the functions of nutrition and reproduction, an account of the varieties of the human race, and the different species of birds and quadrupeds, with a description of specimens in the Royal Museum.

He had a theory of the planetary system, which was one of his favorite doctrines, and which occupies the greater part of his first volume. He believed that the planets were originally a part of the solar sphere, from which they had been struck off, at some time, by the shock of a comet in collision with the sun. The materials of different densities being propelled under this impulse with different velocities, he supposed would naturally collect into spherical masses at corresponding distances from their starting-point, and so give rise to a series of planets moving in successive orbits. Their axial rotation was accounted for by the obliquity with which the comet struck the sun, and the consequent twirling motion imparted to its detached portions.

Wild as this hypothesis sounds, when stated by itself, it was advocated by its author with much force and ingenuity. Even mathematics came in for a share in its support, and it was fortified with arguments from the doctrine of probabilities. As all the planets move round the sun from west to east, and nearly in the same plane, they must all have been set in motion, according to Buffon, at the same time, and by a single impulse. Otherwise, the chances would be as 64 to 1 that the six planets then known would not all move in the same direction; and as 7,962,624[1] to 1 that all their orbits would not be within 7½ degrees of the same plane. He extended the calculation still farther, to the size, distance, and density of the different planets, and to the relation in each between its density and the rapidity of its orbital motion. The figures did not all come out exactly right, but in the case of Jupiter and Saturn the theoretical and actual proportions were very nearly alike, and the author observes with much satisfaction, that "we can rarely obtain from pure conjecture so close an approximation to reality as this."

But the most remarkable production of Buffon's genius was his system of organic molecules, with its associated theories of nutrition and reproduction. According to this view, the bodies of all living creatures, animal and vegetable, were composed of minute particles differing in kind and configuration, but all possessing the general character of vital endowment. These were the organic molecules. As we call a compound group of hydrogen and oxygen atoms a molecule of water, or one of carbon, hydrogen, and oxygen, a starch or glucose molecule, so Buffon seems to have imagined a still more complex molecule having the properties of organic life. These molecules, when associated in the form of an organized body, gave to each part its specific character, and thus provided for the physiological activity of the whole. But they were themselves indestructible, and contained in their own substance the essential principle of vitality. When the animal or plant died and was decomposed, its organic molecules were at once ready to assume new combinations. When one animal fed upon another, or an animal upon a plant, the organic molecules of the creature used as food passed into the tissues of that which devoured it, and when an animal in decomposing, enriched the soil and fed vegetation, its organic molecules were absorbed into the structure of the growing plant. Thus these molecules represented the living elements of the material world. Their quantity was never either increased or diminished. They only passed from one form of combination to another, always transferring their activity from the old organisms to the new. Consequently, there was no such thing as destruction of life in nature, but only continual changes in its distribution. The organic molecules were an exhaustless reservoir of vitality, from which all living beings took their origin, and into which they all again returned.

But nutrition and generation require something more than the mere existence of organic molecules. For even supposing these vitalized particles to be present in full abundance and variety, how could they be arranged in proper order, within the plant or animal, so as form its different organs or enable it to reproduce its like?

This want was supplied by Buffon's celebrated idea of *interior moulds*. It is not easy to say exactly what he meant by this expression, except that it was something capable of arresting the molecules and placing them in a certain combination. "In the same way," he says, "that we have moulds for giving to the outside of things any form we choose, suppose that nature can produce moulds which will determine, not only the external configuration, but also the internal structure of bodies formed in them."

Most readers will perhaps say that this definition of interior moulds is only an analogy, and does not include any intelligible idea of their construction. Buffon himself seems partly conscious of this, and makes a rather labored and metaphysical defence of the term, to show that there is nothing in it contradictory. However that

[1] Œuvres Complètes, Tome xv., p. 336.

[1] Uranus was only discovered in 1781, thirty-two years after the appearance of Buffon's first volume. If the author had included Uranus and Neptune in his calculation, he might have made the chances in favor of his theory as 4,586,471,424 to 1.

may be, the "interior mould" is something which belongs to the entire body and also to each of its separate parts. The whole body is a mould which determines the position and arrangement of its different organs. Each organ, and each part of an organ, when supplied with organic molecules from the food, selects those which are like its own and rejects the rest; while it arranges the incoming molecules in proper order, and incorporates them with its substance, still preserving its original form and texture. In this way the body is nourished and grows, not by addition to its exterior, but by the intimate penetration and selection of appropriate molecules throughout its mass; and all by means of its "interior moulds."

The mysterious phenomena of reproduction were fully explained by the aid of organic molecules and interior moulds. This explanation was even the simplest in cases which we usually consider the most wonderful; as where plants, worms, or polypes reproduce and multiply without sexual generation, by the processes of division or budding. Suppose, in a polype, the organic molecules to be arranged throughout in the form of minute polypes, just as a cube of salt is made up of an indefinite number of smaller cubes, then any part of such an organism, when separated from the rest, will reproduce an entire polype, because it already contains the whole of it in miniature. In an animal or plant which multiplies by budding, the organic molecules absorbed with the food are distributed in due proportion until every part has received its full supply. After that, the surplus molecules are sent back from the different organs and collected in some particular locality, where they form a composite mass, representing the materials of the whole body. Such a mass is a bud; and, when separated from its stock and placed where it can absorb nourishment for itself, it of course grows into an organism like its parent, because it is composed of the same kind of molecules, arranged in the same order, and in the same proportions.

In sexual generation, like that of man and the higher animals, the process is more complicated. Here, again, every part of the body absorbs the organic molecules appropriate to itself, and moulds them into the substance of its own texture. But the excess of material, not required for the nourishment of the organs and returned from them as superfluous, appears in the form of a liquid, and is deposited in a special reservoir. This liquid, made up of contributions from every part of the body, is the seminal fluid. It is a mingled organic extract of the entire frame, and thus contains all the materials necessary for reproduction. Its place of deposit is in the testicles and vesiculæ seminales.

The extreme activity of this seminal fluid, the concentrated essence of the animal organism, is proved by the formation of the spermatic animalcules. According to Buffon, these are not original or essential ingredients of the seminal fluid, but a product of its restless vitality, an incidental form in which its generative power is exhibited.[1] They represent the first assemblage of its organic molecules, as combined into moving particles large enough to be visible by the microscope.

But the female also produces a seminal fluid in the same manner and with the same general qualities as the male. Both fluids, male and female, contain all the elements common to either sex. The only difference between them is that each fluid being a special extract of the body from which it comes, that of the male contains molecules representing the male organs, that of the female those representing the female organs. Buffon entirely rejects the doctrine that viviparous females produce by means of eggs. For him, the ovaries are testicles; the Graafian follicles are reservoirs of nutritious lymph; and the corpora lutea are glandular structures, which produce the female seminal fluid by a process of filtration.[1]

Thus Buffon's theory accounts for reproduction in a very simple manner. Generation is only, in a higher degree, the act of nutrition, operating with the surplus of nutritive material. A mixture of the male and female seminal fluids contains all the organic elements of both sexes, and, therefore, represents the species. In the cavity of the uterus it finds its appropriate nidus and nourishment, and grows into a perfect organism like that from which it came. The theory was supported by abundance of proof; for it explained to a charm most of the important phenomena of generation. 1. During infancy and childhood there is no power of reproduction, because all the organic molecules are taken up by the growing tissues; it is only after puberty, when the body has acquired its full growth, that there is a surplus of organic material, to be filtered through the testicles in the form of seminal fluid. 2. The young child or animal usually resembles both its parents, because its substance is derived from both the male and female seminal fluids. 3. Creatures of small size, like insects, mice, and guinea-pigs, have a numerous progeny, because the demands of nutrition are easily satisfied, and there is a large superfluity left for reproduction; but those of greater bulk, such as man, the horse, the elephant, produce only a single young one at a time, and at long intervals, since the nourishment of their own bodies takes up most of the organic molecules of the food. All these facts were plainly in accordance with the new system.

Indeed, the only difficulty about Buffon's theory (if it is not a contradiction to say so) was that it made the matter too easy. If the seminal fluid of the male contains all the organic molecules necessary to make an embryo, why does it not make one? Why should not the male be self-producing? And why should not the female, on the other hand, have a progeny of little females from her own seminal fluid without the necessity of impregnation by the male? According to the theory of organic molecules, every adult animal produces a fluid capable of generating young. But, in point of fact, the female must also receive the fluid of the male; and, without the concourse of the other, each sex remains barren.

This is the great difficulty in Buffon's way; and, to do him justice, he does not try to conceal or evade it, but struggles with it manfully for sixteen octavo pages. The reader almost feels a sympathy for him when his system of reproduction, after running so smoothly everywhere else, is arrested by so bulky an obstacle as the fact of sexuality. His explanation is full of ingenious hypotheses, but it is very complicated, and leaves in the chain of evidence so many gaps and contradictory possibilities that it is hardly worth while to remember it. Nevertheless, the author thinks too well of the system to have his faith in it shaken by one or two imperfections. The main part of it, he says, he has "proved by so many facts and arguments, that to doubt it is hardly possible." He does not doubt it himself, and he avows that he "entertains no uncertainty whatever as to the basis of the theory, after careful scrutiny of its principles and the most rigorous estimate of its consequences and details."

Buffon's system has its widest extension and most splendid success in the dim regions of equivocal and spontaneous generation. His organic molecules are the genuine repositories of life; the interior moulds of particular organisms being only the means of arranging them in special forms. And when, by the death of an animal, and the decomposition of its body, its organic

[1] Œuvres Complètes, Tome ix., p. 335.

[1] Ibid., p. 345.

molecules are released from the constraint of their interior moulds, they are set at liberty, living and active as ever, to be disseminated in any direction where chance may carry them. In this condition they are the universal seed of nature; without any character of specific organization, but containing all the prolific force of the bodies from which they came. After a time they are absorbed by some other mould, animal or vegetable, into which they transport their own indestructible qualities of nutrition and life. But during the interim, after leaving the old organism and before their incorporation into the new, they form by their reunion a multitude of living structures which do not belong to any of the ordinary or recognized species in nature. Such are the moving corpuscles of the seminal fluid, the microscopic fungi and infusorial animalcules of organic solutions, and, in their larger varieties, the eels of starch-paste and vinegar, and even earth-worms, mushrooms, and entozoa. All these creatures come by spontaneous generation. They are the connecting link in nature between the simple organic molecule, on the one hand, and the complete animal or plant on the other. This exuberant force of production is always in activity. Notwithstanding the death of any number of existing creatures, the total quantity of life on the globe cannot be diminished even for a moment; for it continues uninterrupted in the organic molecules, which pass and repass, from the animal to the vegetable, and from the vegetable to the animal, or produce in the interval an endless variety of spontaneous generations.

No doubt Buffon was in love with his system, and admired it for its own sake. Still, he had a fair share of what Condorcet calls the "sentiment of his own superiority," and ends one of his chapters in a strain that sounds, at this day, rather exalted. "I will add nothing more," he says, "to these reflections. To be accepted, or even to be comprehended, they require a profound acquaintance with nature, and complete freedom from prejudice; so that for the majority of my readers, a longer explanation would still be insufficient, and for those who can understand me, it would be superfluous."

When Buffon's work appeared, it attracted at once the curiosity and applause of the public. The reviewers praised it as "an honor to both the age and the nation."[1] Hume said that its author "gave to things, no human eye had seen, a probability almost equivalent to proof;" and Needham declared that his investigations on the seminal fluid would be a subject of admiration "for centuries to come." All his readers, however, were not of that opinion. There were some who did not accept the doctrines of the book, and who feared that its popularity might have a bad effect. Buffon's high position, his magnificent style, and his confident tone of assertion, alarmed his adversaries, and made them dread his influence on the public mind. His theory, they said, was "filled with dazzling paradoxes, as disastrous to the principles of science as the mines of a skilful engineer to the solid ramparts of a fort." This difference led to a warm discussion. The Abbé de Lignac wrote an anonymous treatise against Buffon's work, under the title of *Letters to an American*,[2] where he criticised the system of moulds and molecules, and said that, instead of describing natural objects, it contained only "the philosophical dreams of M. de Buffon." Buffon's friends, on the other hand, denounced the "American Letters" as a lampoon. They accused de Lignac of having written it out of envy, and to punish Buffon for not showing more respect to his friend Reaumur. Deslandes called the book an imposture, because it was entitled *Letters to an American*, when it had not been written, in the form of letters, to anybody; and because the title-page bore the imprint of Hambourg, though it was really printed at Paris. "That makes no difference," replied de Lignac, "the only title-page that can be called an imposture, is one that promises something the book does not contain; like a natural history, for instance, made up of disjointed and extravagant systems, without anything natural about them."

Buffon's critics were especially dissatisfied with the organic molecules of the seminal fluid, and their wonderful capacity for uniting into an embryo. "If these molecules," they said, "are indifferently the elements of a plant, a man, a dog, or a polype, how can they combine to make either? We might as well go back to Epicurus and his atoms." One of them was asked, by an admirer of Buffon, which he would rather be, the author of the *Histoire Naturelle* or that of the *Lettres Américaines*. He replied that he would rather be an organic molecule, because then he would have more intelligence than either of them. Buffon held his own against these attacks without making any direct reply. His literary talent alone was almost enough to secure him the victory; and if his opponents denied the truth of his theory, they generally had nothing better to offer in its place.

The only real investigations at that time which seriously threatened Buffon's system were those of Haller on fecundation and development. They first appeared in 1753, four years after Buffon's first publication. Haller had examined the ovaries of sheep both before and after impregnation, and observed the condition of the Graafian follicles and corpora lutea. Since corpora lutea, according to Buffon, were glands for producing a seminal fluid, they must, of course, be formed before impregnation and could only open, to discharge their fluid, at the time of conception. Haller declared that there were no corpora lutea in the ovaries during the period of heat, nor immediately after conception; at which time there was nothing to be seen but a simple orifice leading into a ruptured follicle. The glandular structure of the corpus luteum was only formed some days afterward, and, therefore, could not have furnished anything essential to conception.[1] We now know the accuracy and value of these observations by Haller, and can hardly understand how those of Buffon should have been so preposterously incorrect. But at that time it was difficult to decide between them. Both were men of high scientific reputation, and the system of organic molecules was too promising and seductive to be surrendered at the first attack.

But, as time went on, it began to suffer from its own defects. After thirty or forty years' trial, its promises had not produced anything, its obscurities had not been cleared up, and the organic molecules were still as hypothetical as ever. One of Buffon's tenets for explaining reproduction by division, was that the simpler organisms, like plants and polypes, were composed of particles in the form of their own miniature, and he had argued at great length that this kind of structure, if we only thought so, was as simple as any other. Malesherbes[2] finally concluded that it would be of no use to think so, because the thing itself was impossible. "To be convinced of this," he says, "let any one try to draw a picture of this pretended polype entirely made up of similar polypes; or let him get a quantity of little wooden or ivory figures in the form of polypes, and then see whether he can put them together in any way so as to make an entire polype of the same shape. I defy him to do so."

Buffon's interior moulds had no better luck in the end. When it came down to genuine matter of fact, no amount of verbiage could make it plain what sort of things they were nor how they operated. Malesherbes declared that the very idea of a mould is that of something which acts by its surfaces; and that consequently the hypothesis of interior moulds is a mere metaphysical subtlety, without any real application. "To make use of interior moulds, therefore, for explaining the process of nutrition or development, is to solve one difficulty by another; it accounts for one thing by supposition of a second no more intelligible than the first. The truth is, it does not really give any explanation at all; it only answers, like the doctor in Molière, '*Opium facit dormire quia habet facultatem dormitivam.*'"

Another cause of decline for Buffon's system, towards the end of the last century, was the progress of opinion in regard to spontaneous generation. At that time there was much investigation on this subject, especially as to the infusorial animalcules. Needham and Spallanzani were the principal disputants in this field, and attracted to it for some years the attention of the scientific world; the result being at last, a general conviction that Spallanzani's experiments had destroyed the hypothesis of spontaneous generation, at least for the infusoria. The system, therefore, diminished in importance, because this mysterious department of reproduction, which it had explained so well, no longer needed explanation. It thus lost one of its strongest claims to support; and, without being actually disproved, it was discredited to an extent which must have seriously impaired its scientific status.

Finally, it received its death-blow in 1827 from De. Baer's discovery of the ovule in the ovarian follicle of mammalians.[1] De Graaf had supposed, when he first described the ovarian follicles, one hundred and fifty years before, that they were really eggs, and this view was widely accepted. The ovaries of mammalians, like those of fishes and birds, were regarded as clusters of eggs, held together by intervening tissue. But it was not easy to demonstrate, in man and quadrupeds, the discharge of these supposed eggs from the ovary. No observer had ever succeeded in finding one of them separated from its ovarian connections; and the earliest ovum discoverable, in the uterus or Fallopian tube, was of course considerably smaller than the ripe follicle in the ovary. This threw a doubt over the doctrine of De Graaf, and left room for Buffon's assertion that there were no such things as eggs in the mammalian female; that her so-called ovaries were testicles, as much so as those of the male, and that she produced a seminal fluid, composed of organic molecules, similar to his.

This view was so interwoven with Buffon's whole system, that one could hardly exist without the other, and when the microscopic ovum and its mode of exit from the ovary were at last fully brought to light, so that any one could see them when he chose, the discussion necessarily came to an end. The female testicles and seminal fluid, with their glandular corpora lutea, no longer had a place in court; everything connected with them shared in the collapse, and the entire company of organic molecules, reproductive extracts, composite organisms, and interior moulds disappeared together, like actors at the end of a play.

Another set of ideas, once in high repute, was Bonnet's theory of the *Inclusion of Germs*.

This system was somewhat subsequent to Buffon's, though its author was for many years his contemporary. Bonnet was of a wealthy and influential family in Geneva, where he passed the whole of his life, engaged in the study of natural history and kindred subjects. He became widely known for his attainments in this direction, and was connected with nearly all the learned societies of Europe. He was the friend and correspondent of Reaumur, Haller, Spallanzani, Trembley, and De Saussure. Spallanzani communicated to him in manuscript, for perusal and advice, his own researches on the generation of infusoria; and when the volume appeared, he printed, as part of it, Bonnet's letters in reply.[1]

The personal character of Bonnet had traits of superior excellence, and secured him a large share of attachment and esteem. His disinterestedness and modesty, in regard to his own opinions, were well known, and were often the subject of marked eulogy. He attributed the principal credit for his discoveries in entomology to Reaumur, because he had been inspired by the example and encouragement of this master, under whom he felt "proud to enroll himself as a pupil." Spallanzani calls him the "Philosopher of Geneva," and the "sublime author of the contemplation of nature." His first publications appeared in 1745, and were followed by others at various dates until 1770, after which they were collected in a series of eighteen volumes.[2]

Bonnet presented the curious spectacle of a man under the varying influence of two opposite tendencies; at one time an exact and painstaking observer of nature, at another an irresponsible wanderer in the vaguest of speculations. His earliest scientific work was an experimental investigation on the reproduction of aphides, by which he first demonstrated with certainty the non-sexual viviparous propagation of these insects.[3] It is hardly possible to imagine a more thorough, direct, and conscientious method than that adopted by Bonnet in these observations. He took the young aphis, just expelled from the body of its parent, placed it upon a sprig of fresh leaves, stuck in a pot of earth and covered with a bell-glass, and then watched his solitary prisoner for twenty-one days, until it had grown to maturity and had produced, without fecundation, ninety-five young ones. During this time he kept exact records of the insect's moulting and also of the new births, most of which took place under his own eye. He repeated the trial with aphides of different species, and with those which had themselves been produced in captivity; and he succeeded in raising them in this way, without fecundation, for eight successive generations. For these observations he received the honor of an election as Correspondent of the French Academy of Sciences. He also made valuable contributions to natural history on the multiplication of aquatic worms by division, on the growth of plants, on the function of leaves, and on the habits of insects.

On the other hand, he constructed, out of his own meditations, a graduated system of things visible and invisible which he called the *Scale of Being*, and which formed the subject of one of his later works, published under the title of *Contemplation de la Nature*. It embraced the structure of the entire universe, from the simple elements of inorganic matter to the "Celestial Hierarchies" of other worlds. According to this system, there are no gaps or sudden variations in nature, but only a continuous series of combinations and modifications in ascending grade. Everything is immediately connected with that which precedes and with that which is to follow it. At the beginning of the volume there is inserted, for the reader's convenience, a printed table exhibiting the regular succession of natural

objects from gaseous substances up to man. The purely inorganic elements in various grades of combination lead to the composite earths, sulphurs, and metallic bodies; thence through the vitriols, or metallic salts, to ordinary saline substances in crystalline form, and thence to compound rocks of heterogeneous structure, like granite and sandstones. Immediately above these are rocks like slate, talc, and asbestos, which exhibit a laminated or fibrous texture, and which may therefore be considered as "the connecting link between inorganic and organic solid bodies." This point is especially important in Bonnet's scheme, for it marks the passage from dead matter to living organisms. It is not altogether what its author could wish, but he makes the best of it by quietly putting its burden of proof on posterity. "It must be acknowledged," he says, "that the transition here is not quite so perfect as in many other cases. It looks as though nature, in this instance, had made a leap, but the gap will undoubtedly be filled up as our knowledge increases in precision and extent."

Once fairly started among organized structures, the scale rises easily through corals, lichens, and mushrooms to plants in general; through the sensitive plant to animals, from insects to snails, serpents, eels, and fish; through flying fish to birds, from birds to bats and quadrupeds, and so on to monkeys, apes, and man. But this extended gradation is not enough for Bonnet. He has also the "Celestial Hierarchies" and the "Gradation of the Worlds," some of which, he is persuaded, are as superior in physical and moral organization to our earth as man is above the ape.

The frontispiece to Bonnet's work is an engraved portrait of the author, taken, as he tells us, when he was "plunged in deep meditation on the restitution and perfectibility of living creatures." It renders, he thinks, his "reflective expression" with much success. One cannot help thinking it fortunate that the artist saw him just when he happened to be meditating on so abstruse a subject.

Bonnet's great theory of reproduction, or the "Inclusion of Germs," appears mainly in his work, entitled, *Considérations sur les Corps Organisés*, with some additional amplifications in the *Contemplation de la Nature*. His thoughts were turned in this direction partly by Trembley's recent discovery of the multiplication of fresh-water polypes by division, partly by his own observations on aquatic worms, and on the reproduction of aphides. He was further strengthened in his opinion by Haller's observations, which appeared in 1758, on the formation of the chick in the fowl's egg.

There were, about that time, three different views entertained as to the nature of sexual generation.

I. The spermatic animalcules of Leeuwenhoek, one or more in number, were arrested in the uterus, and there became developed into embryos. According to this view, the male parent furnished the living germ, the female only providing for its care and nourishment.

II. The seminal fluids of both sexes, when mingled together, produced the embryo, *de novo*, by a mutual arrangement of their organic particles. This was the doctrine of Buffon, and attributed an equal and similar action to both parents.

III. The germ *pre-existed* in the ovary and egg of the female, and was only stimulated to further development by the seminal fluid of the male.

Bonnet accepted the third of these doctrines. He believed in pre-existence of germs, but he gave to the idea a much wider extent and significance. The germ as he understood it was not only a structure capable of being developed into a living creature; it actually contained, within itself and ready formed, all the parts of the future organism. These parts were exceedingly minute, delicate, and transparent, but they nevertheless existed, though as yet imperceptible to the senses. It was only their small size, their softness and transparency, which prevented their being seen. After impregnation they grew larger, more consistent, and more opaque, and then first became recognizable as the organs of the embryo. These organs accordingly were not things of new formation. They only showed plainly, at a certain period of development, what had previously existed in invisible form. The author extended this doctrine without hesitation to its farthest limits. For him every seed contains a plant in miniature. In an animal germ, every organ and tissue, without exception, is already present—the heart, the vessels, the liver, the kidneys, the intestine, the nerves, and the brain. Consequently, there is no such thing as generation, if by that we understand the production of a new being, or even of a new organ. What appears to be such is only the development of something that was in existence beforehand.

These views were adopted by some and rejected by others, the physiological theorizers of the day dividing into two parties, known as the *Epigenesists* and the *Evolutionists*. The epigenesists were those who believed, like Buffon, that the embryo was a new formation, produced by the union of molecules and the successive organization of different parts. The evolutionists,[1] on the other hand, maintained with Bonnet the pre-existence of germs, and insisted that nothing in the embryo was newly formed, but only enlarged and solidified by development.

These notions were sustained in some degree by the discoveries of Haller in the incubation of the fowl's egg. Haller had studied the development of the chick day by day, and had noted the appearance of its different organs and envelopes. His masterly observations on the yolk-sac and its connection with the embryo, were held by the evolutionists to be decisive as to the pre-existence of the germ and its essential parts. "The membrane enclosing the yolk," says Bonnet, "is continuous with the intestine of the chick. The arteries and veins of the yolk are branches of the mesenteric vessels of the fœtus. The blood circulating in the yolk vessels receives its impulse from the fœtal heart. The yolk is therefore essentially a part of the chick. But the yolk exists in the egg before impregnation; consequently, the chick also exists in the egg before impregnation. . . . . This proves incontestably that the embryo is at first a part of the parent fowl, and that its existence is anterior to the time of conception."

Bonnet's assumption of the pre-existence of the embryo, as well as of the germ, was not without a certain plausibility. The organs of the embryo, when first formed, are in fact not only small, but also colorless and transparent; so that they are seen with considerable difficulty, and may even be overlooked for some time after they are really present. Bonnet says, this is the mistake made by the epigenesists. "They estimate the time when the parts of an animal are first created by that at which they first become visible; and whatever cannot be seen, they assume has no existence." But the organs in an imperfect embryo might very easily have been there, though not sufficiently distinct to meet the eye. "Do you wish," he says, "a short and ready demonstration of this? When the lung of an embryo chick is first perceptible to the senses, it already measures ten one-hundredths of an inch. It is evident that with a size of only four one-hundredths it would have been visible, were it not for the extreme transparency of its tissue."

And so on, of all the other parts. Bonnet has more

[1] It is unnecessary to say that this term was used, during the last century, in a sense entirely different from that which attaches to it now.

faith than the epigenesists. He believes that the organs of an embryo were there before he could see them, and that they even existed from the beginning, though invisible, in the unimpregnated egg.

But if the germ contains all the organs of the chick ready formed, only small and undeveloped, it contains ovaries as well as the rest; and these ovaries contain the germs of the next generation. It is plain the series cannot end here. The germs of the second generation are chicks in miniature, as much as those of the first. Consequently, they contain their own ovaries and germs, which in turn contain others still; and so on without any definable limit, one set of germs within the other in geometrical progression, each germ containing not only its own embryo, but also all the embryos that can possibly be produced from it in unnumbered generations hereafter.

Bonnet does not shrink from the magnitude of this spectacle. He rather glories in it, and enjoys the contemplation of its unlimited perspective. "For my part," he says, "I like to extend as far as possible the limits of creation. There is a pleasure in the thought of this magnificent series of organized beings, enclosed, like so many little worlds, one within the other. I see them receding by degrees, diminishing in regular order, and losing themselves at last in an impenetrable night. It gives me a sense of satisfaction, when I look at an acorn, to see in it the germ of a majestic oak that centuries hence will shelter the birds and the beasts under its branches; or still more to behold in Emilia's womb the germ of a hero who thousands of years hereafter will found an empire, or perhaps of the philosopher who shall discover to mankind the cause of gravitation, the mystery of reproduction, or the mechanism of our existence."[1]

This prospect, however, for the germs of the future which Bonnet found so attractive, was not as satisfactory to some of his contemporaries. They even haggled with him about the past. If the age of the world, as generally admitted, was six thousand years, and if each generation of man is completed in thirty years' time, that would give two hundred successive generations since Adam and Eve, with about a thousand million human beings at present on the earth. All these inconceivable members must have been contained under the form of germs in the ovaries of Eve. The minuteness of the embryo of the two hundredth generation, when enclosed in the body of our first parent, was declared to be something incredible. Still more so, for plants which grow and fructify every year. Hartsoeker calculated that the relation in size between the first wheat-grain and that to be produced at the end of six thousand years would be expressed by the figure of unity, *followed by thirty thousand zeros*.

All this did not give Bonnet or his friends any discomfort. Such terrific estimates may serve to confound the imagination, but logic always finds a sure refuge in the infinite or indefinite divisibility of matter. Hartsoeker and his followers, according to Bonnet, put the senses and the imagination in place of the understanding. They want to see and touch, so to speak, what can only be comprehended by an effort of the mind. The hypothesis of the inclusion of germs is above the level of such calculations, and is, he concludes, a "splendid triumph of pure reason over the senses."

Bonnet's theory is by no means confined to the simple hypothesis of one germ included within another. It is an extensive and elaborate system, ramifying into all departments of natural history and physiology. The included germs not only exist before fecundation, but they are nourished, and grow in a way analogous to that of adult bodies. There can be no doubt of this, because the fowl's eggs certainly increase in volume before fecundation, and are to be seen in the ovary of many different sizes and grades. But the yolk is essentially a part of the young chick. Therefore, if the yolk grows before fecundation, the embryo does also. Beside, in the theory of inclusion, the contained germs diminish progressively one within the other, to an inconceivable minuteness. The outermost germ is, of course, the largest, and is nearly ready for impregnation. But when it has been fecundated, and has expanded into the body of an adult female, the next included set of germs have in turn come to be as large as the other was before, and so on in continuous order, the smaller germs gradually moving up in the scale of magnitude, to be ready for impregnation when their time arrives. The process of nutrition and growth must, therefore, be going on in these embryonic organisms, and has been going on in them ever since the creation.

But how is the nutrition of the germs provided for, and what are the materials used in their growth?

It is well known, says Bonnet, that the different parts of the body are not nourished directly by the blood. A more delicate and colorless fluid, called *lymph*, separated from the blood by appropriate organs, serves for the immediate supply of the tissues, and as these tissues vary in fineness and consistency, we can hardly doubt that the secretory organs prepare for them different kinds of lymph, more or less attenuated to correspond with the delicacy of structure in separate parts. Some tissues, as, for example, the brain and nerves, must require a lymph many times finer and more subtle than that employed for the grosser parts.

But the included germs are made up of tissues finer still. If we admit that there is no such thing as real generation, and that everything has been preformed from the beginning, then the germs which are to make their appearance a thousand years hence, have now actually within them, and incalculably minute, all the parts characteristic of the species. Imagine the heart, the brain, the nerves, and the stomach of such an embryo. Certainly, no lymph could penetrate these tissues, or be of the least use for their nutrition. What fluid is there in the body sufficiently attenuated and ethereal to insinuate its particles into a structure of such delicacy, and incorporate them with its substance? There is only one, and Bonnet secures it. This precious and double-distilled material, which is alone capable of nourishing an infecundated germ, is the *nervous fluid*.

The nervous fluid was not an invention of Bonnet's. It was generally acknowledged, in his time, as the immediate cause of nervous action. Like the electric fluid, it was intangible and invisible, and was known only by its effects. Its invisibility was due to its vapors or aerial constitution; and this enabled it to circulate in the delicate passages of the nervous tissue, which were themselves invisible, owing to their minuteness. The nervous fluid, or "animal spirits," so-called, after being elaborated in the brain, was disseminated through the nervous channels to the various organs of sense and motion. Its existence was proved by a very simple fact. If you tie a nerve going to a muscle, the muscle is paralyzed. How could a ligature cut off the nervous influence, except by arresting the passage of a fluid? There was, therefore, little or no doubt in regard to it.

The nervous fluid, in Bonnet's system is not entirely dissipated in the exercise of sensibility and muscular action. The unconsumed portion, after returning to the brain, was again sent out by similar channels, to be used in nutrition. It was carried by the maternal nerves to the ovaries, and there immediately distributed to the germs "of the first order," or those nearest maturity.[1] Elaborated anew and still further spiritualized by the organs of this delicate

[1] Œuvres de Bonnet, Tome v., p. 206.

[1] Œuvres de Bonnet, Tome x., p. 10.

structure, it supplied a finer nourishment to the germs of the second order; here it underwent a similar preparation for those of the third order, and so on, to the belated and unfortunate germ which "would not be ready for fecundation till the end of the world."

This staggering array of infinitesimals, in structure and function, only serves to increase the author's admiration and strengthen his confidence. "What an abyss of wonders," he says, "in the human brain. Even a single fibre of the brain is itself an abyss. What shall we say, then, if all these mysteries, existing in the adult body, are repeated and concentrated in so many organized atoms, enclosed one within the other, and growing constantly smaller, in indefinite progression?"

The act of impregnation, in reproduction by sexes, comes in for a very easy and natural explanation. The nervous fluid is the appropriate nourishment for an infecundated germ. When this germ becomes a fœtus, it will be supplied with lymph, and its organs will grow like those of the adult. But how can it make the transition from one state to the other, and how are the finely woven tissues of the germ-embryo to be made capable of admitting the grosser substance of the lymph? This is exactly the function of the seminal fluid. It is not only a source of nourishment for the mature germ, but it has a special stimulating influence on the embryonic heart. The pulsation of the heart in the germ-embryo is very faint, and only serves for the circulation of the nervous fluid. Consequently, the infecundated germ increases but slowly, and never gets beyond a certain stage of development. But when the seminal fluid comes in contact with it, and penetrates its substance, the heart's pulsation is increased in force. This causes an expansion of the circulatory channels, an increased volume of the circulating fluid, and, consequently, more rapid nourishment; and thus the limit is passed between the condition of the germ-embryo, whose tissues only admit nervous fluid, and that of the growing fœtus, that can thrive upon the lymph. Once begun, the process naturally continues until the body has attained its full development.

Still the theory of inclusion was not altogether free from difficulty. One of its most troublesome problems was that of intestinal worms and other parasites. Bonnet wrote a special treatise on the tænia, partly devoted to different theories of its origin. He rejects, of course, the idea of equivocal or spontaneous generation. But if, like everything else, it comes from pre-existing germs, are these germs introduced into the intestine from without, or did they exist beforehand in the embryonic human body itself? If so, the germ of the first tapeworm, and, in fact, of all which have existed since, must have been included in the body of the first man. There are objections to be met in either case, but the most singular are those connected with the second.

In this view the tænia has a contemporaneous origin with man; that is, it already existed in Adam and has passed so into his posterity. But according to Genesis, the animals were all created before Adam. Therefore, the tænia must have first lived in a foreign element; and the fact is, we never find it except in the intestines. Besides, how can we suppose such a pest to have been placed in the body of our innocent progenitor, living in the earthly paradise of the Garden of Eden? Valisnieri, who adopted the contemporaneous theory, had an odd answer to this objection. He assumed that before Adam's fall the intestinal worms did not do him any harm, but, on the contrary, were rather useful in "consuming the superfluous humors and gently stimulating the intestinal walls." Bonnet thinks this explanation a trifle far-fetched, and doubts whether Adam, in his state of innocence, had any superfluous humors or needed any tapeworm to excite his intestines. He prefers the idea of M. Leclerc, that the intestinal worms, which are now so troublesome, only existed at first in Adam under the form of eggs, and were not hatched until after his disobedience.[1]

But the line of descent for tapeworms is not yet quite clear. Granting that they existed in Adam, either as eggs, or as worms, how did they get into the body of Eve, through which they must have passed, for transmission to posterity? The most direct route from the intestine, according to Valisnieri, would be through the thoracic duct, which "mounts upward along the ribs," to that one which was taken for the body of Eve. Bonnet is inclined to adopt a simpler and less miraculous method of transfer, by supposing that the eggs of the tænia are so small that they can pass through the bloodvessels, and thus reach the vesiculæ seminales. "In this way," he says, with a puzzling kind of *naïveté*, "we can explain the whole thing without much difficulty, and *without having recourse to divine power*."

However, the author regards the introduction of parasitic germs from without as on the whole the more probable theory of their origin, especially as the weight of evidence was already in that direction.

The system of Bonnet has applications to many different points of general physiology, such as the resemblance of the young animal to both parents, the production of hybrids and monstrosities, and in particular to non-sexual generation, or multiplication by budding and division; all of which is explained, with more or less ingenuity and success. It had an apparent support in several recent and important observations; such as the existence in certain seeds, of an embryo plant, the multiplication by interior germs of *volvox globator*, the reproduction of aphides without impregnation, and Haller's researches on the formation of the embryo chick. Haller himself defended it from a variety of objections, and adduced a number of arguments in its favor.[2] But the theory itself went so far beyond the limits of possible demonstration, that its basis of reality bore no calculable proportion to its towering superstructure. It discounted the results of embryological discovery at too exorbitant a rate; and it could not afford to have any of them turn out differently from what was expected. This happened in the case of the mammalian egg. Subsequent observations, made with better facilities, showed that the organs of the fœtus do not pre-exist in the ovum, in the sense imagined by Bonnet. The impregnated ovum has, it is true, a remarkable property, by which each separate part assumes afterwards a definite shape, and becomes a distinct organ. But the actual configuration of these organs is certainly not present in the ovum, because we can now see its original structure, as well as the intermediate forms which are to be replaced by those of the future embryo. The system of the inclusion of germs, in the time of its glory, embraced the whole history of the world from beginning to end, and the mechanism of growth and reproduction throughout the organized creation, it claimed for its support the results of scientific discovery, and of logical deduction; but it came to grief when the study of embryology had reached a certain stage in its development, and had demonstrated the actual constitution of the mammalian egg.

DILATATION OF THE STOMACH AS A DIAGNOSTIC MEASURE.—Dr. ROSENBACH suggests, in the *Deutsche Med. Wochenschrift*, No. 2, 1882, the distension of the stomach with carbonic acid developed from the action of the Seidlitz powders, taken separately, as a valuable means of examining the condition of the stomach and as a fixed boundary for study of the abdomen.

ON THE

INFECTIOUS CAUSES OF INFLAMMATION.

Two Lectures delivered at the Pathological Institute of the University of Leipsic, December 8 and 9, 1881.

BY PROF. JULIUS COHNHEIM.

LECTURE II.

(Reported for the MEDICAL NEWS, by special permission of the Author, by Dr. WALTER MENDELSON.)

GENTLEMEN: We were speaking, yesterday, of the investigations of Koch and others into the nature of anthrax. Let us now continue the subject by considering some of the causes of other infectious diseases. Though we have progressed very far into the knowledge of the virus of anthrax, the investigations of the causes of the great majority of the other infectious fevers have so far not been crowned with a like success. It is true that in a number it has been possible to find minute organisms in the blood of those affected, but in no other case (if we except trichinosis) can we trace the whole connection between these microphytes and the disease, as has been done in anthrax. A decade has elapsed since Obermeir found in the blood of patients suffering from relapsing fever certain wavy, thread-like bodies, the *spirillæ*. Their presence in the blood was observed to correspond to the relapses of the fever, the febrile state persisting so long as they remain and becoming less intense as they diminish in numbers, while during the intermissions no spirillæ can be found. Koch and others have made experiments with a view to propagating them, but so far without results. In typhoid fever, Klebs and Eberth have found a bacillus, which they claim to be the specific virus. You all know that micrococci have been found in the intestines and dejecta of typhoid-fever patients for a long while; but I need hardly tell you that such exist in the intestines and fæces of healthy persons, and are of no significance. These two investigators, however, have succeeded in finding in the lymphatic glands and vessels in the vicinity of the typhoid ulcers, rod-shaped organisms, bacilli, which are somewhat smaller than those of anthrax. Klebs and Tommasi-Crudeli, of Rome, have found a somewhat longer bacillus in patients suffering from malarial fever, and they have not only found them in the patients, but in the soil of the malarious districts. In lepra, Neisser, of Leipsic, has discovered a bacillus existing in the nodes on the skin, which is very much smaller than any of the foregoing, requiring a very high magnifying power to become visible. He found them quite constantly, lying closely packed together, and to their increase he attributes the growth and distention of the nodes. Many years ago, Hansen, a Norwegian, described what he supposed to be the specific leprosy germ; but what he saw were simply micrococci, and certainly, by the methods he used, it is impossible to demonstrate the bacilli found by Neisser. Neisser has further discovered the specific virus of gonorrhœa, this time a micrococcus; and Klebs has published at various times the existence of microphytes in a number of infectious diseases, among which I might mention syphilis and lobar pneumonia; and although other investigators have not always had the same success in finding them, and thus confirming their existence, still, any statement coming from this excellent authority must be looked upon with the highest consideration.

Opposed to those who seek for each infectious disease its virus in a well-defined and separate germ, there are a certain number who deny the specific nature of these pathogenic fungi, but hold that the same species, differing in form during different generations, both morphologically and physiologically, may cause the different infectious diseases. At the head of this school stands Nägeli, of Munich, who with his pupils has labored hard to uphold this theory; a theory which I hope to be able to show you later, gentlemen, will not bear the test of close critical investigation. Even though this view were correct, the parasitic hypothesis of the nature of infectious diseases would of course be in no wise affected; still, it is a question too pregnant of interest to be passed over in silence. If we consider the question of the changeability of the pathogenic organisms, surely you must agree with me that, from the point of clinical experience alone, we must reject such a view. We know that there is no class of diseases more definite in their course than the infectious ones, none whose individuality is more clearly stamped upon them. As far back as we have any trusty records at all, measles has always been described with the same symptoms that it has to-day; scarlet-fever the same; and so on I might multiply instances; and although it is true that in certain epidemics some symptoms appear more prominently than others, and even that in the course of centuries, certain infectious diseases have become modified in some particulars, still, it is unheard of that these diseases should have changed any of their characteristic features, or that one should even have become transformed into another. There exists not one reliable record of the contagion of measles producing aught but measles, or that a small-pox patient ever infected any one with anything but small-pox; and though there have been attempts, from time to time, to show that measles in one has produced scarlet-fever in another, and *vice versa*, yet, in the few cases which have been adduced in support of this assumption, it has usually been a question of the rash of measles becoming so confluent as to resemble that of scarlatina. Similarly, typhus and typhoid have been compared, but it seems to me that their only points of resemblance lie in their names.

Now, if it were really true that the different infectious diseases were caused merely by different forms of the same fungus, it would certainly be justifiable to suppose that the changes from one form to another might take place in the patients themselves, and that a case beginning, say as measles, should end as scarlet-fever or as diphtheria, or some other zymotic disease, or, at least, that an epidemic should change its nature in the course of its career. It is, however, almost superfluous to say that such an occurrence has never been noticed.

Conclusive proof of the mutation of form could only be furnished by actual observation and experiment on the schizomycetes themselves, and this Buchner has tried to afford. A work recording his observations appeared last year, and, as it contained some apparently startling revelations, it created a great sensation at the time. By repeated propagations he affirmed that the highly virulent *bacillus anthracis* could be changed into the harmless hay bacillus, two microphytes whose appearance and metamorphoses exactly resemble each other. Were this true, it would indeed be a striking and most important fact, but, unfortunately, his observations have not been confirmed by other investigators.

It is only a few weeks ago that the results of the labors of Koch and some of his pupils have been published, which entirely and conclusively upset Buchner's statements. They show that Buchner did not observe the needful precautions to eliminate from his experiments all sources of error, for, by observing the necessary care, Koch was able to propagate either bacillus indefinitely, without the slightest change taking place in its nature. Indeed, the very methods which Koch used as far back as 1878, to obtain one kind of bacillus free from admixture of others, go to prove the untenability of Buchner's views. He found that when a putrid fluid from any source was inoculated into the wounds of rabbits, mice, or other animals, one kind of the many schizomycetes originally present

finally gained the upper hand, and produced a certain form of traumatic disease. If another animal was now inoculated from the individual so affected, that form of bacillus was invariably found which had in the first instance gained the ascendancy. If we take these facts, combined with those furnished by clinical medicine, into consideration, I think we will have good grounds for believing that the separate characteristic infectious diseases correspond to equally separate and characteristic forms of fungi, or, to express it a little differently, that each infectious disease owes its peculiarities and typical course to the vital attributes and development of the organism which causes it.

Another thing which speaks very strongly in favor of a differentiation, is the *incubation* stage noticed in infections. In the great majority a certain period of time elapses between the reception into the system of the virus and the appearance of symptoms, and during this period of *latency* or *incubation*, the patients usually feel in good health, or at least show no *specific* symptoms. Still another, and even more remarkable fact, is that in each disease the stage of incubation is of a different length, and that in each it lasts a definite number of days. I really hardly know of any more striking evidence in favor of the parasitic theory of the causes of infectious diseases in general, and specific nature of the separate pathogenic germs in particular, than is given us by this century-old experience. It can certainly not depend on the quantity of virus introduced into the system, that measles invariably appears on the ninth to eleventh day after infection, but rather that the virus needs this period of time in order to develop to a morbific agent. Anthrax only becomes apparent when the spores have developed to bacilli, and the symptoms of trichinosis, the fever and myalgia, make themselves noticeable only after the intestinal trichinæ have developed from those eaten with the infected meat, and from these a new generation has been hatched. The number of trichinæ introduced may modify the degree and intensity of the disease, but never its typical course.

Thus everything seems to point to a *contagium vivum*, against which no other valid objection can at present be raised than that in so many infectious diseases its existence has not as yet been absolutely demonstrated.

If we now apply all that we have been discussing to the infectious forms of *inflammations*, I think we may formulate our knowledge thus: that the alterations in the vascular walls of certain localities, which result in changes in the circulation leading to inflammations, are due to schizomycetes. The reason that these fungi establish themselves, after getting into the system generally, in one particular organ or part of the body, depends, no doubt, on the same reason that the trichinæ born in the intestines are finally found in the muscles, namely, that in no other place do they find a material suitable to their nourishment. However much this assumption may be justifiable, you must still not forget, gentlemen, that it is by no means proved, and affords material merely for a provisional and elementary hypothesis. In what manner the schizomycetes react upon the walls of the vessels, it has as yet hardly been attempted to explain.

In the case of the putrefaction bacteria and the micrococci, we thought the inflammatory changes produced were due to a chemical decomposition of the fluids of the body dependent on their increase and growth. It may be possible that in the case of the specific germs of the infectious diseases, similar chemical changes are produced in the vascular walls of the parts where the germs are localized. If this be really a fact, if it be indeed true that cerebro-spinal meningitis, for instance, is caused by certain schizomycetes finding their necessary nourishment in the pia mater, and here causing, by their growth and development, such chemical changes that the walls of the capillaries of the pia become altered in their structure, it seems to me we are entitled to look upon the metastatic inflammations and abscesses of pyæmia as a particular subvariety of infectious inflammation, and of such a kind, indeed, which distinguishes itself from all other forms of infectious diseases by the fact that it owes its origin to *fungi which seem to exist everywhere and at all seasons*. In this way we can readily explain that although a wound can, in any part of the world, become infected, or that even erysipelas or pyæmia may appear sporadically, as it is termed, yet that these diseases are also at the same time markedly contagious, as only too many instances have proved. The germs exist everywhere, it is true, but the liability of infection increases, of course, if a wound be brought near a person whose body presents a more than usually rich breeding-ground.

We see, therefore, that the old idea that the infectious diseases might appear in any place or at any time can no longer be maintained; yet, after all, this limitation relates to a point of but very subordinate importance, and which has really as little true connection with the nature of the diseases as their classification into contagious, miasmatic, and miasmatic-contagious. For us, gentlemen, the thing of chief importance, in speaking of infectious diseases, is the parasitic nature of their morbific causes, or, as we may also say, the organized nature of the virus, and we know to-day that, aside from exceptional cases, it depends on the biological peculiarities of these parasitic organisms whether they enter our systems by way of the water we drink, the air we breathe, or from already infected individuals. Since these side issues of the general question have been more closely studied, the number of diseases which can be classed as infectious has, in the last decade, slowly but steadily increased, and many are now reckoned in this group whose true etiology was not even suspected a few years ago. To show you how compatible the present parasitic theory is with the always known clinical history, let me merely bring to your minds a familiar instance. That a coryza—a simple catarrh of the nose or throat or larynx, or, as it is generally called, "a cold"—is quite markedly contagious, has long been recognized by both the public in general and by physicians. Yet how could a disorder having such marked powers of reproduction ever be produced by changes of temperature, wind, rain—in short, atmospheric conditions of any kind? A confirmation of the correctness of our views, of still greater weight, has been furnished us by a more close and critical examination of the anatomical and clinical histories of cases. This has shown that many inflammations, formerly looked upon as independent, are in reality directly connected with infectious diseases. In pleuritis and peritonitis, pathological anatomists have maintained for some time this relation. For many cases of endocarditis and meningitis, too, this view obtained. Quite lately Wagner, of Leipsic, basing his statements on his large clinical experience, has come to the conclusion that the great majority of inflammations of the kidney develop secondarily to some infectious disease which has preceded them. Similar proofs have been given for chronic bone and joint inflammations by Lücke, and for the internal inflammations of the eye by Leber. If you will bear in mind, too, that by the progress of pathological anatomy, certain formerly unexplained inflammations, such as the congenital valvular lesions from intrauterine endocarditis, certain lesions of the spinal cord, etc., have been shown to be of a non-inflammatory nature, it will be at once evident to you that the number of inflammations depending on

inexplicable and incomprehensible causes is rapidly diminishing. If for an etiology of inflammation we are not yet in a position to entirely discard the idea of a *rheuma*, that is, an abnormal condition of the skin or mucous membranes or other organs of the body, produced by atmospheric conditions, it seems to me that the science of medicine is at least on the best way to do so.

THE USE OF CONSTITUTIONAL REMEDIES IN THE TREATMENT OF EAR DISEASES.[1]

BY SAMUEL THEOBALD, M.D.,

MEMBER OF THE AMERICAN OTOLOGICAL SOCIETY; SURGEON TO THE BALTIMORE CHARITY EYE AND EAR DISPENSARY; OPHTHALMIC AND AURAL SURGEON TO ST. VINCENT'S HOSPITAL, BALTIMORE.

THIRTY years ago Sir William Wilde (then Mr. Wilde), of Dublin, in a chapter devoted to the consideration of otorrhœa, in his excellent work upon Aural Surgery, wrote as follows: "With regard to general treatment, a very remarkable difference seems to exist in this country in relation to the management of the diseases of the eye and the ear; that of the former being of too local a nature, while that of the latter is almost exclusively constitutional. How frequently do we see a case of pustular or rheumatic ophthalmia, with a foul, white, loaded tongue, treated by a caustic solution dropped into the eye, or an astringent lotion applied to the eyelids; while a case of otorrhœa, without any derangement of the digestive functions or general health, is recommended tonics, sea-bathing, blistering, and an issue in the arm."[2]

Sir Wm. Wilde was an eminent teacher, and probably as much as any man aided in shaping the development of modern otology, and it may be that this criticism of his upon the exclusively constitutional treatment of ear diseases prevalent at the time he wrote, produced a more radical effect than he intended. However this may be, if he were with us to-day, I feel quite sure that his complaint would be, not that constitutional remedies are used to the exclusion of local ones in the treatment of ear diseases; but, on the contrary, that with pendulum-like swing, we have gone to the other extreme, and that now upon local means too great reliance is placed, while the value of constitutional treatment is almost lost sight of. For, though this distinguished author inveighed against the neglect of local means in the management of affections of the ear, he was at the same time a firm believer in the value of internal medication, and one may find in a single chapter of his thoroughly practical treatise more said in commendation of constitutional remedies than he will discover between the covers of some of the works upon ear diseases written within the past ten years. It is, indeed, true that much of Wilde's constitutional treatment consisted in what nowadays would be regarded as an unjustifiably free use of mercury; and, although he speaks with abhorrence of the reckless manner in which this drug had been administered twenty years before his day, allusion to very sore mouths occurs with somewhat unpleasant frequency in the reports of his cases. But there *are* conditions in which, I believe, much is to be gained by following his example more closely than we do, even in this particular.

The very recently issued works upon diseases of the ear, by Dr. A. H. Buck,[3] of New York, and Mr. Dalby,[4] of London, may be referred to as affording proof of what I have said as to the slight importance attached to the use of constitutional remedies by recent writers upon diseases of the ear. Dr. Buck, it is true, does not ignore constitutional remedies to the same degree that Mr. Dalby does; nevertheless, he damns them with faint praise in eczema of the auricle; speaks only of quinia, iron, and bark in furuncular inflammation, and of Fowler's solution in diffuse inflammation of the external auditory canal, and says of the latter, he has had too little experience with it to express a decided opinion regarding its efficacy; recommends as "general measures" in middle-ear catarrh nothing except change of air, adequate exercise, attention to the diet and cold sponge-baths, and bromides for the relief of tinnitus; suggests nothing beyond local treatment in acute purulent otitis media but rest and a non-stimulating diet, unless it be due to syphilis, when, in addition, "constitutional remedies" should be administered; mentions only iodide of potassium in deafness due to non-specific disease of the labyrinth, but speaks with favor of the "vigorous antisyphilitic treatment" recommended by Dr. Roosa when the labyrinthine affection is of specific character; and, most noteworthy of all, concludes his exceedingly interesting and instructive chapter upon "Diseases of the Mastoid Process" by devoting six pages to the question of "treatment," *without making one single allusion to internal medication*. One might be disposed to conclude that this failure to speak of anything besides local measures, in considering the treatment of mastoid affections, is the result of an oversight upon the part of the author; but the description given of the treatment adopted in the numerous cases of this character which he reports, renders it probable that such is not the case, but, on the contrary, that it is a true index of his convictions.

This seems the more remarkable, because at least one of the cases related illustrates in a striking manner what, under the most unfavorable circumstances, active constitutional treatment is capable of accomplishing. The case I allude to[1] is that of a little girl, six years of age, in whom alarming cerebral symptoms developed in connection with a severe attack of acute inflammation in the drum of each ear. The inflammation had lasted one week when Dr. Buck was called in. He found the patient slightly delirious, with a temperature of 105° and a pulse of 140. There was almost total deafness, and both tympanal membranes were red and swollen, the right one bulging somewhat superiorly and posteriorly. The mastoid region showed no external signs of disease. Dr. Buck made "a free incision" into the posterior half of each membrane, giving vent to no pus, and prescribed only the warm douche, to be used freely, and poultices. On the following day the child was in a state of partial coma; the temperature had not improved; pulse 140, and feeble; sordes upon the teeth; tongue dry; and no discharge from either ear. Drs. Markoe and James R. Wood were now called in consultation, and at their suggestion "mercury was administered: internally, in the form of calomel in small doses; externally, in the form of inunctions of the oleate of mercury (10 per cent.), frequently repeated. Bromide of potassium was also given, in conjunction with the calomel." The next morning, Dr. Buck goes on to relate, the child was "very much better, an active discharge having established itself in both ears during the night;" and "from this time onward"—as he subsequently learned from her physician—"she made a rapid recovery, and regained her hearing almost perfectly." The lesson which this case teaches is so plain, it seems to me, that he who runs may read. Dr. Buck, however, does not appear to

[1] See page 307 of Dr. Buck's book. The case occurred in January, 1876.

have been impressed by it; at least, the method of treatment so successful in this instance was resorted to by him in but one other case,[1] and then only in the last extremity, when from the "advanced stage of the cerebral disease" and the absence of redness and tenderness behind the ear, "it seemed unlikely that any relief would be afforded by the operation of perforating the mastoid process." As may be supposed, the mercurial treatment here, was of no avail, and the patient died two or three days later.

With each succeeding year of experience, I have learned to place a higher estimate upon the value of internal medication in the treatment of diseases of the ear, until at the present day I resort to constitutional remedies with nearly the same frequency, and almost the same confidence in aural, that I do in ophthalmic practice. And here I may remark, in parenthesis, that this result is due in no small degree to my experience in dealing with eye diseases; for, assuredly, nowhere do we find more distinct and convincing proofs of the efficacy of constitutional remedies than in ophthalmic practice.

At the head of the list of remedial agents in which experience has taught me to place confidence in diseases of the ear, I do not hesitate to put the once much abused in practice, and later scarce less abused in precept, drug —*mercury*. It has not been very many years since mercury was freely employed in the treatment of ear diseases. Wilde, as we have seen, used it with great freedom, and Toynbee also prescribed it very often. Of late, however, the tendency has been to resort to it only when there is reason to believe that the local malady is dependent upon or complicated by *syphilis*. "Mercury," says Sir Wm. Wilde, "is the medicine which, of all others, acts most beneficially in diseases of the ears, simply on account of its specific efficacy in arresting or controlling inflammation or removing its products."[2] And if we admit, as I am quite prepared to do, that mercury has such "specific efficacy," we need only call to mind the minute anatomy of the ear—the peculiar character of the membrane, mucous membrane and periosteum, at once, which lines the tympanal cavity and mastoid cells, and of that, fibro-serous in structure, which invests the intricate walls of the labyrinth—to appreciate that here, of all places, in an inflammation involving such structures, a peculiarly favorable field is open for its action.

Of the value of mercury, more especially the bichloride, *in chronic and subacute inflammation of the middle ear*, Wilde speaks in the most positive terms;[3] while Roosa, on the other hand, with equal positiveness condemns its employment under such circumstances, and says, "the time has probably gone by when a person in fair health, suffering from chronic aural catarrh, and who has no constitutional taint, will be treated by alterative doses of the bichloride of mercury, followed by the iodide of potassium."[4] Although I have the highest regard for Dr. Roosa's opinions, and esteem him a thoroughly practical surgeon, I should be extremely sorry to think that the future would verify this prediction of his, for my own experience leads me to endorse heartily the views of Wilde, and to believe *that in giving up mercury we should lose the one remedy which we can least afford to do without*. And I may add that I am also prepared to endorse what he has said in the same connection as to the perfect safety which attends even the long-continued administration of the bichloride of mercury, when it is prescribed in doses proportioned to the susceptibility of the patient. The *biniodide*, however, is the preparation of mercury which I more frequently employ, in both ophthalmic and aural practice. The addition of two grains of iodide of potassium to each grain of the biniodide of mercury renders it freely soluble in water, and in this form I usually prescribe it, giving, according to circumstances—the susceptibility of the patient and the nature of the malady—from $\frac{1}{24}$ or $\frac{1}{12}$ of a grain to $\frac{1}{10}$, $\frac{1}{12}$, $\frac{1}{8}$, or even in some instances $\frac{1}{6}$ of a grain of the mercury salt, three times a day.[1] In deafness due to middle-ear changes, unless I have reason to think the patient will be unusually sensitive to its action, I commonly begin by prescribing $\frac{1}{32}$ or $\frac{1}{24}$ of a grain, to be taken three times a day, after meals; and very often when only slight, or perhaps no appreciable improvement follows its administration in these doses, together with careful local treatment, which should never be neglected (but into the consideration of which the limits of this paper do not permit me to enter), a marked change for the better *does* become manifest *when the dose is increased to* $\frac{1}{10}$ *or perhaps* $\frac{1}{12}$ *of a grain*. Occasionally, in persons who are peculiarly susceptible to the action of iodine, I substitute with advantage, and in similar doses, the *bichloride of mercury* for the biniodide solution; and, on the other hand, I sometimes increase the proportion of iodide of potassium in the latter, so that a full dose of it may be given with the mercury.

The employment of mercury is especially indicated, and its good effects are more manifest in that variety of middle-ear catarrh so frequently encountered, which least deserves to be called *catarrh*, in which the tendency is towards sclerosis and thickening, and in which the fibrous structures of the tympanum are, perhaps, chiefly involved. Often, however, even in true mucous catarrh, we shall accomplish more with it than with any other drug, although in this condition I usually employ, instead, the muriate of ammonia, of which I shall presently speak.

It is, perhaps, scarcely necessary for me to state here, and yet I think it will be more discreet to do so (for there is nothing leads so surely to circumspection, and this to introspection, as a little wholesome criticism), *that I have not confounded syphilitic and non-syphilitic cases of middle-ear disease*, and that what I have said, so far, as to the value of mercury in chronic and subacute tympanal catarrh has reference *only to cases of non-specific character*. When, as we so often find, these middle-ear maladies *are* dependent upon constitutional syphilis, inherited or acquired, then, of course, all that has been said as to the propriety of administering mercury, and the good which it is capable of accomplishing, may be repeated, as to them, with twice the emphasis. In this connection I may state that my uncle, Dr. Alan P. Smith, whose opinion is valuable because of his large experience and habit of observing closely,

[1] Op. cit., p. 320, Case XIV.

[3] Ibid, p. 210.
[4] Treatise on Diseases of the Ear, New York, 1873, p. 289.

[1] At the present time I have a man (a German, 46 years of age, by occupation a shoemaker) under treatment for neuro-retinitis, who, since November 2, 1881, has taken *every week four grains* of the biniodide of mercury ($\frac{1}{24}$ gr. three times a day) with the happiest effect as regards his vision, and without the slightest disturbance of his general health or interference with his daily occupation. He had been taking strychnia in full doses for some time before coming into my hands in January last; but, according to his report, with no benefit to his sight. He was allowed to continue the strychnia, and, in addition, was given the biniodide, in the solution above described, $\frac{1}{12}$ grain to be taken three times a day. When this treatment was commenced, he could with difficulty decipher words of J. No. 12. Subsequently the dose of biniodide was increased upon several occasions, until, upon the date mentioned, the present quantity was reached. With each increase in the dose (there being no change in the strychnia dose), a more marked improvement in vision became manifest, until at the present time he can make out short words of J. No. 1, and read No. 2 with tolerable fluency. He denies syphilis, and there seems to be no good reason for considering the affection of specific character. This is, in my experience, an instance of exceptional insusceptibility to the action of mercury, although Wilde speaks of giving ¼ grain of the bichloride for "months together" without unpleasant consequences.

tells me that in chronic nasal catarrh, even when it occurs independently of syphilis, he has obtained more satisfactory results from the long-continued administration of small doses of the biniodide of mercury than from any other plan of treatment which he has tried.

In *inflammation involving the nervous apparatus of the ear*, whether of specific or non-specific origin, mercury, in the form of the biniodide is, in my opinion, by far the most valuable remedy that we possess. In opposition to the views of a recent writer upon this subject, I believe that syphilis, both inherited and acquired, *very frequently invades the labyrinth*, although, undoubtedly, the middle ear is at the same time often (but not always) involved. If I were asked to state what, in my opinion, are the most frequent causes of nervous (labyrinthine) deafness, I think I should have no hesitation in answering: first, cerebro-spinal meningitis; next, *syphilis*; and, after that, traumatism. I have not had the good fortune to see any cases of deafness from cerebro-spinal meningitis improve under treatment; possibly some of those which I have met with might have been benefited by mercury if they had been seen at an earlier period. That very much may be accomplished in syphilitic disease of the labyrinth, sometimes even when the deafness is of considerable duration, by the persistent administration of moderate doses of the biniodide of mercury, I have convinced myself in a number of instances. I have also obtained better results from this remedy in Ménière's disease, uncomplicated by syphilis, than from anything else that I have employed.

It is a question in my mind how far the administration of mercury is justifiable *in that form of acute inflammation of the tympanum which, if allowed to run its course unchecked, usually ends in suppuration, in perforation of the drumhead, and in the establishment of a more or less persistent otorrhœa.* Practically, as these cases seldom come into the hands of the specialist until after the period is passed at which this plan of treatment might be resorted to with advantage, he is not often called upon to decide this point. Of course, in this condition, alterative doses of the biniodide or bichloride would be of little avail, and, so far, I have not met with cases in which I have felt called upon to administer calomel or blue mass so as to impress the system. I have, however, given purgative doses of calomel in combination with rhubarb, or with rhubarb and scammony, in acute inflammation of the middle ear with the happiest effect. And I believe that when the inflammation is intense, becoming a *periostitis* rather than a catarrhal inflammation of a mucous membrane, when there is marked constitutional disturbance, and, above all, when symptoms of cerebral irritation make their appearance, I believe, that under these circumstances, considering how great is the danger of meningitis supervening, it is our duty, without loss of time, and in addition to local antiphlogistic treatment (of which the free application of leeches will form a chief part), to bring the patient quickly under the influence of mercury; and this we shall accomplish best by administering at short intervals small doses of calomel, combined, if need be, with opium, and occasionally, perhaps, by supplementing this with inunctions of the oleate or the officinal ointment of mercury. For is it not to be desired rather that the patient should recover, somewhat "pulled down," it may be, by the active treatment he has received, but with a sound ear, than that he should be suffered to die from meningitis or cerebral abscess, or, at best, get over the acute attack with a permanently damaged ear, and a persistent otorrhœa to remind him of what he has gone through with, and to be a standing menace to the integrity of his brain for the rest of his days?

(To be continued.)

ON THE ANTIPYRETIC TREATMENT OF TYPHOID FEVER.

BY AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

THE following are the tables referred to in the lecture on the antipyretic treatment of typhoid fever, contained in the first number of the MEDICAL NEWS (January 7, 1882). They embrace the data on which were based the conclusions presented in that lecture. In each table will be found

1. The number of times, during the continuance of the disease, that the different modes of refrigeration, namely, the ice-bath, the sponge-bath, the wet sheet, with sprinkling, were employed.

2. The temperature in the axilla whenever either of these modes was employed.

3. The duration of the employment of each of these modes whenever employed.

4. The temperature in the mouth when the employment, at each time, was concluded.

5. The duration of the antipyretic effect in every instance.

The number of tables, corresponding to the number of cases, is fifteen. It is needless to say that the records made of the cases, and the tabulation of the facts, have required considerable labor, which, it is hoped, will not be without value as data having reference to the antipyretic treatment of typhoid fever.

CASE NO. 1.—RECOVERY.

Modes of Employment of Cold.	Axillary Temperature when Commenced.	Duration of Employment	Temperature in Mouth at Conclusion.	Duration of Antipyretic Effect.
Ice-bath.	105°	1½ hrs.	103¾°	1½ hrs.
"	105°	½ hour.	102°	2 hrs.
"	105°	1½ hrs.	103°	1 hour.

Sponge-bath.	105°	6 hrs., at intervals.	102 1-5°	Not noted.
Ice-bath.	105¾° in rectum.	Not noted.	Not noted.	Not noted.
Sponge-bath.	104 1-5°	3½ hrs.	102°	1 hour.
"	103 1-5°	1½ hrs.	103 1-5°	Not noted.
"	104°	1 hour.	103¾°	Not noted.
Sponge-bath.	103½°	6 hrs.	102¾°	

Subsequently, in this case, 7 sponge-baths were given on the next day; 7 the next day; 8 the next day, and 5 the next day. After 7 days 32 baths were given in one day, and 2 on the day following. After 21 days, 3 baths were given during one day; 2 daily on the next 3 days, and 3 on the next day. These subsequent baths are not tabulated, for the reason that in many instances the time of their continuance is not noted.

The number of ice-baths given in this case is 5, and the number of sponge-baths 46.

CASE NO. 2.—RECOVERY.

Ice-bath.	103½°	15 minutes.	101°	1½ hours.
"	104°	An hour.	102°, and subsequently in 2½ hrs. 101°	15 hours.
Sponge-bath.	103°	Not noted.	101°. 5 h. after conclusion, 99°	6 hrs. after reduction to 99°
"	102¾°	"	102°	
"	103½°	"	102°	12 hrs. after reduct'n to 102°
"	10[illegible]°	"	101¼°	

In this case, 7 additional sponge-baths were given, the details not having been noted.

The number of ice-baths is 2, and the number of sponge baths is 11.

CASE NO. 3.—FATAL.

Wet sheet.	104°	One hour.	102¼ °. An hr. and a quarter after conclusion 101°, and after another hour 100°.	Four hours.

In this case pneumonic symptoms were present on the day but one following the employment of the wet sheet, and death took place four days afterwards. The temperature rose to 108° on the day of death.

CASE NO. 4.—RECOVERY.

Wet sheet.	103½ °	2 hrs.	103°. An hour and a half after conclusion, 102¼ °; and in 4 hours, 100¾ °.	No rise of temperature except for an hour once during ten days.
"	103½ °	2 hrs.	102½ °	1 hour.
"	103½ °	4 hrs.	102°	48 hours.
"	103½ °	4 hrs.	102½ °	24 hours.
"	103¾ °	4 hrs.	102½ °	No further rise of temperature to 103°.

CASE NO. 5.—RECOVERY.

Wet sheet.	104½ °	4 hours and 45 minutes.	101¾ °	2 hours.
"	105½ °	6 hours.	103½ °	1 hour.
"	105¾ °	6 hours.	104°	Owing to delirium and complaining by the patient, cold not employed for 18 hours.
Sponge-bath.	105°	2 hours.	103¾ °	Afterward the temperature did not call for antipyretic treatment.

CASE NO. 6.—RECOVERY.

Wet sheet.	104¾ °	1 hour.	102¼ °	2 hours.
"	104¾ °	1 hour.	102°	3 hours.
"	104°	2 hours.	102°	1 hour.
"	103¾ °	1 hour.	Not noted.	Not noted.
"	104°	2 hours.	101¼ °	2 hours.
"	104¼ °	1½ hrs.	101¾ °	1½ hrs.
"	105¼ °	2 hrs. and 45 mins.	101½ °	2½ hrs.
"	104°	2 hours.	101½ °	1 hour.
"	103°	50 mins.	102°, and in 2 hrs. after conclusion, 101¼ °.	6½ hrs.
"	103½ °	30 mins.	101¼ °	5 hours.
"	103°	45 mins.	101¾ °	4 hours.
"	103¾ °	25 mins.	101¾ °	2½ hrs.
"	103¾ °	1 hour.	101¼ °	13 hours.
"	103½ °	45 mins.	101¼ °	3 hours.
"	103¾ °	35 mins.	101°	20 hours.
"	103¾ °	40 mins.	101°	5 hours.
"	103¾ °	1 hr. and 25 mins.	101½ °	Subsequently no rise of temperature to 103°.

The wet sheet was employed in this case 13 times.

CASE NO. 7.—RECOVERY.

Wet sheet.	104½ °	20 hours.	103½ °	Wet sheet discontinued, owing to antipathy of patient.
Sponge-bath.	103½ °	6 hours.	102¼ ° in axilla. 14 hours after sponge-bath 101¼ °.	4 hours.
"	103¾ °	Not noted.	Not noted.	Not noted.

In this case the temperature several times afterward rose to 104°, but was always reduced by the sponge-bath.

CASE NO. 8.—FATAL.

Sponge-bath.	104¼ °	30 minutes.	102¾ °	9 hrs. 103¾ °, and 16 hrs. 104°.
"	104 1-5°	20 minutes.	102½ °	9 hrs. 103¾ °, and 18 hrs. the same.
"	103¾ °	20 minutes.	101¼ °	2 hours.
"	104¾ °	20 minutes.	102°	2½ hrs.
"	104½ °	20 minutes.	101¾ °	9 hrs. 103½ °, and 12 hrs. 104°.
"	103½ °			

The patient became comatose, and died on the second day after discontinuance of the antipyretic treatment.

CASE NO. 9.—RECOVERY.

Sponge-bath and rubbing surface with ice for ten minutes.	104⅛ °	1 h. and 10 min.	102°	2 hours.
Sponge-bath.	104°	25 minutes.	Not noted.	3 hours after sponge-bath.
"	104¾ °	45 minutes.	103¾ °	Rubbed with ice immediately.
Rubbing surface with ice.	104⅛ °	101¾ °	101¾ °	2 hours.
Sponge-bath, and rubbing with ice 20 minutes.	103¾ °	30 and 20 min.	101½ °	In 5 hours 103°

In this case, for 5 days after last sponge-bath and rubbing with ice, the temperature was generally under 103°, and cold was not employed. Then the temperature rose to 103½°, and the sponge-bath in 20 minutes reduced it to 102¾°. Subsequently, the sponge-bath was employed 13 times, and the surface repeatedly rubbed with ice, always with reduction of the temperature.

CASE NO. 10.—FATAL.

Sponge-bath.	104¾ °	20 min.	102°	2½ hours.
"	104¾ °	30 min.	No reduction of temperature.	
Wet-sheet.	104¼ °	2 hours.	102½ °	8½ hours.
"	104¼ °	8 hours.	103°	2 hours; temperature 105°; and in 6 hrs. fell to 101°, without any antipyretic treatment. In 5 hrs. rose to 104°, and an hour later to 105°.
Sponge-bath.	105°	1 hour.	102¾ °	6 hours.
"	105°	2 hours.	103°	3 hours.
"	105°	2 hours.	102¼ °	13 hours.
"	104°	3 hours.	102¾ °	3 hours.
"	105°	1½ hrs.	102¾ °	2½ hours the temperature was 105°, and in 1½ hours fell to 102¾ °, without antipyretic treatment. In 36 hours afterward it rose to 104°.
"	104°	1½ hrs.	102¾ °	20 hours.
"	105°	8 hours.	102¾ °	15 hours.
"	105⅛ °	11 hrs.	103°, and 2 hours after 102°.	In 11 hrs. the temperature rose to 105°, and in 4 hours fell to 103¾ °, without antipyretic treatment. In 18 hours rose to 104°. Death 11 hrs. afterward, the temperature remaining at 104°.

CASE NO. 11.—FATAL.

Wet sheet.	104¼°	3 hours.	102¾°	23 hours.
Wet sheet in "Kibbe's cot."	103¾°	1½ hours.	103°	26 hours.
"	103¾°	5 hours.	102¾°	13 hours.
"	103¾°	4½ hours.	102½°	16 hours.
"	103¾°	45 minutes.	102½°	6 hours.
"	103½°	1 hour.	102°	2 hours.
"	103½°	3 hours.	102¼°	5 hours.
"	103¾°	4 hours.	102½°	6 hours.
"	104¼°	7 hours.	102¾°	4 hours.
"	103½°	2½ hours.	102°	5 hours.
"	103¾°	4 hours.	102½°	3 hours.
"	104°	17½ hours.	103°	4½ hours.
"	104¼°	2 hours.	102¾°	3 hours.
"	103¾°	3 hours.	102°	4 hours.
"	104°	3 hours.	102¼°	4 hours.
"	104°	3 hours.	102°	2 hours.
"	103¾°	3 hours.	102½°	4 hours.
"	103¾°	7 hours.	101½°	14 hours.
"	103½°	2 hours.	102°	80 hours.
"	103¾°	1 hour.	102½°	4 hours.
"	104¼°	3 hours.	102½°	4 hours.
"	104°	2 hours.	102¾°	12 hours.
"	103¾°	1 hour.	102¾°	4 hours.
"	104°	3 hours.	103½°	4 hours.
"	103¾°	3 hours.	102°	15 hours.
"	103½°	1 hour.	102½°	Quinia substituted and bath suspended for 24 hrs.
Sponge-bath.	104¼°	2 hours.	102½°	
Sponge-bath and 20 grs. quinia.	104¼°	3 hours.	102°	21 hours.
"	104°	1 hour.	103¾°	
"	103¾°	12 hours.	101½°	12 hours.
Sponge-bath and 15 grs. quinia.	103¾°	2 hours.	102¼°	2 hours.
Sponge-bath and 20 grs. quinia.	103¾°	2 hours.	102¾°	14 hours.
Sponge-bath.	103°	2 hours.	102½°	4 hours.
Sponge-bath and 20 grs. quinia.	104°	1 hour.	103½°	1 hour.
Sponge-bath.	104⅛°	1 hour.	102⅛°	2 hours.
Sponge-bath and 20 grs. quinia.	103⅛°	4 hours.	102¾°	11 hours.
"	103¾°	2 hours.	101°	6 hours.
"	103¾°	9 hours.	102½°	3 hours.
Sponge-bath.	103¾°	1 hour.	103°	3 hours.
Sponge-bath and 20 grs. quinia.	104°	4 hours.	103°	4 hours.
Sponge-bath.	103¾°	2 hours.	103°	6 hours.
Sponge-bath and 20 grs. quinia.	104¾°	3 hours.	103°	3 hours.
Wet sheet in "Kibbe's cot."	104¾°	2 hrs. and 25 minutes.	102¾°	3½ hours.
"	104½°	2 hours.	102½°	8 hours.
Sponge-bath and 15 grs. quinia.	104¼°	1 hour.	103°	3 hours.
Wet sheet in "Kibbe's cot."	104¾°	2 hrs. and 25 minutes.	102¾°	4 hours.
"	104⅛°	2 hours.	102⅛°	3 hours.
"	103⅛°	1 hour.	102¾°	16 hours.
"	103⅛°	4 hours.	102⅛°	

Death took place 4 hours after the last employment of the wet sheet, the temperature just before death being 103°. The wet sheet was employed 32 times and the sponge-bath 17 times.

CASE NO. 12.—RECOVERY.

Sponge-bath.	103⅛°	35 min	102⅛°	2 hours.
"	104°	40 min	103½°, and afterward declined to 99½ (3 hours).	8 hours.
"	105°	1 hour	102°	3 hours.
"	103¾°	45 min	103°, and in 2 hrs. afterward fell to 102¼°.	Subsequently no rise of temperature to 103°.

CASE NO. 13.—RECOVERY.

Sponge-bath.	103⅛°	3 hours.	102°	13 hours.
"	103⅛°	2 hours.	102¼°	9 hours.
"	103°	1 hour.	101⅛°	12 hours.
"	103¾°	3 hours.	102°	2 hours.
Wet sheet.	103¾°	11 hrs.	At end of one hr., 104°; continued for 3 hrs. longer, 102½°; continued for 7 hrs. longer, 102°; and in 1 hour after removal of sheet, 101°.	No further rise of temperature to 103°.

CASE NO. 14.—RECOVERY.

Sponge-bath.	104°	1½ hrs.	105⅛°. The wet-sheet then substituted.	
Wet sheet.	105⅛°	6 hours.	102¾°. 3 hours after removal of sheet, 99¾°.	40 hours.
"	104°	4½ hrs.	102°	No further rise of temperature to 103°.

CASE NO. 15.—RECOVERY.

Wet sheet.	103¾°	10 hours.	At end of 3 hours, 105¾°. In 7 hrs., 102°.	6 hours.
"	103½°	6 hours.	At end of 1 hr., 104°. At end of 10 hrs., 101¾.°	15 hours.
"	103°	1 hr. and 45 min.	102¾°. In 15 min. after removal of sheet, 101¾°.	8 hours.
"	104°	4 hours.	102¾°. In 2 hours after removal of sheet, 101°.	No further rise to 103°.

HOSPITAL NOTES.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

A SERIES OF CASES OF ANEURISM.

(Reported by WILLIAM E. HUGHES, M.D., LATE RESIDENT SURGEON.)

(*Concluded from page 101.*)

CASE IV. *Aneurism of External Carotid Artery.*—Service of Dr. AGNEW. Mrs. Serina M. P., white, æt. thirty-eight; admitted June 25, 1881. Four years before she had received an injury in the neck near the left angle of the jaw, by being thrown from a carriage. The injury apparently consisted of a slight abrasion and contusion, and nothing was thought of it at the time. Three weeks afterwards, a small tumor was felt at the site of the contusion, which, however, gave her no pain or uneasiness. It grew rather rapidly, and soon the characteristic signs of an aneurism became manifest. Two years after the appearance of the aneurism, an artery in the neck (probably from the patient's description of the operation, the external carotid), was ligated, which, for a short time, arrested the pulsation and bruit. They recurred, however, after a short interval, and the tumor continued to grow. A short time before admission she had several hæmorrhages from the mouth, which were easily controlled by the application of styptics to the bleeding points. When admitted, the tumor extended from the ear to the angle of the mouth, measuring eight inches in that direction; had pushed in the cheek; encroaching on the cavity of the mouth, and pressed on the jaws to such an extent as to render the taking of any but liquid food a matter of great difficulty. Pressure on the left common carotid

artery controlled pulsation perfectly. Dr. Agnew tied the left common carotid June 29, 1881. The tissues were found much matted together, as if by previous inflammation, and it was with great difficulty that the vessel could be separated from its sheath. After the ligature had been placed around the common carotid below the omo-hyoid muscle, it was found that pulsation in the aneurism, though lessened, was not entirely controlled. The incision was carried higher, and the trunk of the external carotid bared. In cutting down to the artery, several large veins were opened. Two silk ligatures were passed around the artery; these included the external carotid, the superior thyroid, lingual and facial arteries, and the bleeding veins. This last ligation controlled the pulsation perfectly. For the first three days after the operation, the tumor remained quiet and relaxed, no pulsation or bruit could be detected. There was perceptible lessening of the swollen veins of the forehead, and the measurement from ear to angle of mouth was one-half inch less than it had been. At the end of three days pulsation and bruit became manifest, and it was evident that blood was finding its way into the sac by means of the other carotid and circle of Willis. Pressure on the left carotid no longer controlled the pulsation, but pressure on the right did so perfectly. To exclude the current of blood flowing into the sac through the right common carotid, this vessel was tied by Dr. Agnew, August 6, 1881, thirty-eight days after the ligation of the left. The same matted condition of the tissues was found as was present on the left side of the neck, the superficial arteries were much enlarged, and several of them had to be tied before the carotid was reached. The silk ligature was passed around the artery above the omo-hyoid muscle; it was tightened slowly, several minutes being employed, in order to cut off the supply of blood to the brain as gradually as possible. The patient reacted well; there were no cerebral symptoms manifested, except a partial loss of memory and slight incoherence in the expression of her thoughts. These lasted about three days, when the mind became perfectly clear, after which she complained that objects were not sharply outlined. The failure of vision remained about the same till her death, but was not at all marked. No ophthalmoscopic examination was made. For the first week the tumor remained quiescent; at the end of that time a bruit became audible, very much fainter, however, than the original one. There was no pulsation; the wound did well, the ligature coming away on the twelfth day. The slight bruit persisted though the tumor, diminishing decidedly in size, measured six and a half inches from the ear to the angle of the mouth, and encroached so much less on the mouth, that the jaws could be much more widely separated than before, and solid food taken with ease. On September 4, a small ulcer, apparently aphthous in character, appeared in the mucous membrane of the mouth, over the prominence produced by the aneurism. A few days later, a gush of blood came from this ulcer, but was easily controlled by plugging the cavity with dry lint. On September 9, a much more serious hæmorrhage occurred, but it too was at length controlled by additional plugging. There was no recurrence of hæmorrhage, but four days later a fetid, sanious fluid commenced to ooze through the plugging. The plugging was removed without the occurrence of any hæmorrhage; symptoms of septicæmia set in, and she died September 15, 1881, eighty-four days after the original ligation.

CASE V. *Femoral Aneurism.*—Service of Dr. AGNEW. Joseph M., white, æt. thirty; admitted August 29, 1881. Patient was a moulder, having much heavy lifting to do, and often carrying heavy loads pressing on his groin. He had not had syphilis. About a year before, while pushing a heavy casting, his feet slipped, and something gave way in his left groin. Shortly afterwards, he noticed a small pulsating tumor. On admission, the aneurism had attained quite a large size. It was on the left femoral artery, apparently originating immediately beneath Poupart's ligament, and extending down the leg five inches. The leg was swollen and œdematous, and could be moved only with intense suffering. Owing to the weakened state of the patient, and his inability to endure the pressure of an abdominal tourniquet, ligation of the external iliac artery was determined on. On dissecting down to the artery, Dr. Agnew found that the aneurism had pushed up Poupart's ligament, and had involved the trunk of the external iliac artery for a distance of an inch above the ligament. A carbolized animal ligature was passed around the trunk of the external iliac, and the wound closed. The wound healed by adhesion throughout one-half of its extent, the other half remaining open and suppurating freely. The aneurism remained perfectly quiescent for about a week; at the end of that time, a faint pulsation, but no bruit, appeared, lasting for a few days, when it ceased, and the tumor remained quiet. The swelling of the leg disappeared in the course of two weeks, and the patient was able to move without pain. The wound healed slowly, and is now almost closed. The tumor contracted gradually, the leg below the tumor resumed its natural appearance, and the patient is now practically well. The tumor, however, remains soft, and there may still be some danger of suppuration.

CASE VI. *Femoral Aneurism.*—Service of Dr. ASHHURST. Wm. S. D., colored, letter-carrier, æt. thirty-nine; admitted October 1, 1881. He could not ascribe the origin of the aneurism to any injury; he had not had syphilis. Thirteen months before admission he noticed a small hard lump, about as large as the end of his little finger, at the apex of Scarpa's triangle in the right leg. At first it gave him no trouble, but about four months after its appearance, he began to have slight pain in it, and the leg grew gradually weak, so that he was unable to go on with his employment. On admission, an aneurism, about as large as a small walnut, was found seated on the right femoral artery at the apex of Scarpa's triangle; there was marked pulsation, but no thrill, and only a very indistinct bruit. Pressure on the femoral artery above the aneurism, stopped the pulsation completely, and the tumor became smaller, and very soft and flaccid, showing that there had been little, if any, deposition of laminated clot. The pulsation in the aneurism being thus easily controlled by pressure, it was determined to try digital compression. Pressure on the femoral artery below the origin of the profunda femoris, was commenced in the evening, and continued, uninterruptedly, for ten and a half hours, when a horseshoe tourniquet was substituted for the finger. Pressure by the tourniquet was maintained about twelve hours, when the finger was again resorted to. Digital compression was this time kept up for eight hours (eighteen and a half hours in all), by which time pulsation had ceased, and the tumor was hard and firm. The patient was placed at rest, and all pressure taken off. The tumor remained firm, contracting somewhat, and about three weeks after his admission, the patient was discharged cured.

Remarks.—In looking over the foregoing cases, certain conclusions present themselves. First, as to the etiology. Syphilis was absent in every case, and probably plays a less important rôle in the causation of aneurism than is often claimed for it. In four of the cases (I., III., IV., V.), the origin of the aneurism could be traced distinctly to a local injury to the vessel, while in case VI., it was probably due to some strain or injury received while walking. In case II., the

history was so indefinite as to preclude even a conjecture as to the origin of the aneurism.

As to treatment, the results show that treatment by digital compression is infinitely safer than ligation of the vessel. The two cases (II., VI.) treated by compression recovered rapidly, without an adverse symptom or complication; while of those ligated, two (III., IV.) died and one (V.) recovered. And it does not seem necessary to keep up digital compression unremittingly, but it can be substituted, without much retarding the cure, by pressure made by a tourniquet. Compression, by means of Esmarch's bandage, proved futile in the one case (III.) in which it was tried.

MEDICAL PROGRESS.

Treatment of Goitre by Iodoform.—M. Boéchat has employed iodoform in the treatment of goitre (*Correspondenz, Blatt für Schweizer, Aerzte I., S. 12*): 1. External applications; the author made use of a glycerole of iodoform, which he protects by a coating of collodion. His results were negative in old, cystic, or parenchymetous goitres; in recent goitres, of soft consistence, on the other hand, the tumors diminished more rapidly than with either iodine or iodide of potassium; the odor, however, is a great inconvenience.

2. Internal use of Boéchat prescribed iodoform in pill of ⅙ grain, not to exceed ten daily. This treatment was only made use of in two cases of goitre of long standing, and his results are not stated.

3. Interstitial injections. M. Boéchat has made use of this method in three cases. The first case had had a goitre from infancy; the half of a Pravaz syringeful of a saturated solution of iodoform in ether was injected daily for fifteen days, and although the tumor diminished considerably in size, the treatment had to be abandoned on account of the inflammation produced. In the second case, two injections were sufficient to produce improvement in a case of long standing. In the third case, one of long-standing suppuration was produced without any other change.—*Journ. de Méd. de Paris*, Dec. 24, 1881.

Syphilis of the Heart.—Dr. Mayer (*Prak. Arzt., No. 4*) states that the symptoms of syphilitic affection of the heart are like those of the weakened heart of Stokes, or of chronic diffuse myocarditis. He describes the case of a patient who exhibited the symptoms of cardiac insufficiency without evident valvular disease. He had had syphilis eight or nine years before, periostitis was present in the leg, and the mouth was also affected. Treatment by mercurial inunction and iodide of potassium effected a complete cure.—*Practitioner*, Jan., 1882.

Atropia in Menorrhagia and Hæmoptysis.—Dr. Tacke (*Berliner Wochenschr.*, 1881, No. 6) considers atropia a much more certain remedy in menorrhagia and hæmoptysis than ergot. He was led to apply it in these conditions by injecting it subcutaneously in a woman suffering from eczema, and who had at the same time a profuse menstrual flow. He injected $\frac{1}{100}$ of a grain twice daily for two days. The eczema was greatly benefited, and the menstrual flow was much reduced. He recommends a solution of sulphate of atropia 1 to 1000 of water. Five minims to be injected two or three times a day subcutaneously.—*Practitioner*, Jan., 1882.

Excision of the Tarsal Arch.—Excision of the tarsal arch has been now so often performed for obstinate cases of club-foot, that some material for forming a just appreciation of its value exists. The questions that arise are these: Are there cases of club-foot in which the usual treatment by manipulation fails? If so, is excision of the tarsal arch the best means of dealing with them? Can this operation be wisely substituted for the milder treatment in other simpler cases? As Mr. Hayward insisted at the Clinical Society, there are very few, if any, cases *in children* in which tenotomy and judicious and long-continued after-treatment will not accomplish cure; and we hope to see this operation reserved entirely for adults, in whom the deformity of the bones and other changes have rendered other methods of treatment useless. In patients of the poorer classes, however, there is another consideration to be weighed—that is, time. A successful excision of the arch effects a cure in a few months, while an obstinate case in a child, ten years of age, say, may require as many years of skilful treatment by other means; and when the effect of the treatment is such that a cripple becomes able to compete successfully with his fellows in almost all kinds of labor, the question of time is of serious moment. But in suitable cases it is open to doubt whether the results of this operation are superior to those of Chopart's amputation, which is its alternative, while it would seem that its dangers are greater. Mr. Davy has lost by death one out of seventeen operations, and König has lost one out of three, both patients dying from septicæmia. The danger, then, of excision of the tarsal arch ought effectually to prevent its being substituted for the more general treatment of club-foot in simple cases, even although it cures in a shorter time; and it certainly has not yet been demonstrated that its results are superior to those of amputation, which is safer. It is eminently a case in which a judicial investigation might be expected to do good.—*Lancet*, Dec. 24, 1881.

Malformations in the Region of the Omphalo-mesenteric Duct.—Prof. Roth (Basel) concludes an interesting article (*Virchow's Archiv.*, Bd. 86,) on malformations in the region of the omphalo-mesenteric duct, with the following summary of those hitherto observed:

1. The common *diverticulum ilei* (Meckel) which usually hangs free in the abdomen, but may be found in a hernia or in the folds of the mesentery.

2. The adherent diverticulum; the union, by means of a blind end or a cord, is commonly at the navel, more rarely at other points in the abdomen.

3. The open diverticulum; the orifice being at the navel. It may be surrounded by a small prolapse of the wall, or a red, saccular prominence, or there may be prolapse of the bowel.

4. The diverticulum is the starting point of retention tumors-enterocysts, which may retain a connection with the bowel or be isolated.

Ammoniacal Peptonate of Iron.—To prepare this solution, MM. Jaillet and Quillart recommend the following formula: Dried peptone, 5 grammes; sol. of perchloride of iron, 6 grammes; neutral glycerin, 50 grammes; cherry-laurel water, 150 grammes; water of ammonia, q. s. Dissolve the peptone in 50 c.c. of cherry-laurel water, and then add the glycerin; then dilute the officinal (French) solution of perchloride of iron with 50 c.c. of cherry-laurel water, and mix the two solutions; then add ammonia drop by drop until a flocculent precipitate is formed, which dissolves on a further addition of ammonia. It should, however, be avoided having the ammonia in excess. Finally, add enough cherry-laurel water to bring the mixture up to 200 c.c., which will therefore contain two mgrm. and a half of iron in each Pravatz syringeful.

In these conditions the peptonate of iron has not the styptic taste of the perchloride, and when injected

hypodermically at the body temperature produces neither pain nor inflammation. It is also interesting to notice that the peptonate of iron does not give the reactions of iron with the ordinary reagents.—*Bull. Gén. de Thérapeutique*, Dec. 30, 1881.

THE INDICATIONS FOR TREPHINING IN FRACTURES OF THE CRANIUM.—From an interesting review of this subject, with the study of several cases, M. G. FELIZET concludes:

1. That far from adding to the gravity of a wound of the head, with circumscribed depression and fracture of the internal table, antiseptic trepanning is a perfectly harmless procedure.

2. The operation can only be governed in its execution by rules which vary with the circumstances of the case; it has the advantage of transforming a complex and dangerous wound, and one liable to infection, into a simple, antiseptic wound, and one easily examined. —*Arch. Gén. de Méd.*, Jan., 1882.

PILOCARPINE IN DIPHTHERIA.—From the study of a number of cases, Dr. GREZA FALUDI believes the following conclusions to be warrantable:

1. Pilocarpine, administered internally, is a remedy of incontestable value in diphtheria.

2. Pilocarpine will always be useful in inflammatory affections of the mouth or pharynx, on account of its property of producing excessive salivation. Nevertheless, it does not appear to be superior to chlorate of potash or chloride of iron, and can by no means be regarded as a specific.

3. It is especially of service in light cases of diphtheria when the affection is limited to the buccal and pharyngeal cavities.

4. Unfortunately, it does not prevent the morbid process from invading the larynx and respiratory passages, and then a fatal termination is usually to be expected.

5. When this invasion of the air-passages occurs, then pilocarpine is of no value.

6. When administered to young children, its consecutive depressive effects must not be lost sight of; under such circumstances stimulants should be associated with it.—*Bull. Gén. de Thérapeutique*, Dec. 30, 1881.

LUMBAR COLOTOMY.—At the meeting of the Société de Chirurgie, held December 28, M. TILLAUX stated that he agreed entirely with the opinion of M. Trélat, expressed at a previous meeting, that although a lumbar artificial anus was much more difficult to establish than one in the iliac fossa, it was much less dangerous than the latter, as all danger of peritonitis was avoided, and besides it incommoded the patient less. He also presented a patient on whom he had operated three years previously according to this method, for stricture of the rectum of inflammatory origin. An interesting point in the case was that the patient always experienced a desire to defæcate before the escape of the contents of the bowel, and was able voluntarily to restrain for a time any fæcal evacuation.

M. TRÉLAT also presented a case on whom he had operated a month before for cancer of the rectum; the effects of the operation had now passed off, and the fatal result had undoubtedly been postponed.

M. DEPRÈS stated that he had never seen a case of cancer of the rectum in which this operation could be required, and he had usually no difficulty in passing the entire hand through strictures of the rectum which were inaccessible to the finger. When he finds a case suffering from symptoms of obstruction, he applies a blister to the abdomen, and places the patient in a warm bath, as he cannot comprehend the utility of this operation in patients condemned to die from cancer.

M. LABBÉ said that he had made use of this operation for more than three years, and was more than ever impressed with its value, especially when the artificial anus was established in the lumbar region. He was surprised at the opinion of M. Deprès, for, although without doubt the cancer continued to develop, symptoms of obstruction were removed, pain was relieved, and he believed that life under such circumstances was prolonged for from eighteen months to two years.—*Gaz. Méd. de Paris*, Dec. 31, 1881.

VESICANTS IN PLEURISY.—From a study of six cases, Dr. BONAMY thinks that blistering is too much neglected in the treatment of pleurisy, and he believes that both theory and clinical experience justify its use in the decline of the affection. He suggests that perhaps the increase in the mortality from pleurisy noticed in the last few decades may possibly be attributed to this neglect of a valuable remedy.—*Bull. Gén. de Thérapeutique*, Dec. 30, 1881.

TREATMENT OF PERTUSSIS.—Dr. FORCHHEIMER recommends, as a modification of the treatment suggested by Letzerich, the insufflation of quinia, two parts to one part each of bicarbonate of soda and powdered acacia, the powder being blown into the larynx by an ordinary laryngeal insufflator, three or four times daily. The first effect is to cause a new paroxysm of coughing, but it soon passes off, and the beneficial results are usually evident on the fourth day. He reports ninety-seven cases.—*Amer. Journ. of Obstetrics and Diseases of Women and Children*, Jan., 1882.

ON THE SELECTION OF SUITABLE MEDICINES FOR THE GENERAL TREATMENT OF SYPHILIS.—SIGMUND says (*Wiener Med. Wochenschrift*, Oct. 15, 1881), that the choice of a remedy in syphilis is to be determined on when the symptoms of the general disease are such as to afford sufficient indications for the means to be employed and the mode of its administration. Syphilis frequently runs a mild course and gets better spontaneously. Energetic treatment pursued too soon may be injurious, and is useless, while it is impossible by any treatment to obviate the general disease. At the same time, it is all-essential to devote the utmost care to the primary symptoms, to observe dietetic and hygienic rules, and to pay attention to any concomitant diseased conditions. Specific "antisyphilitic" measures are, in his view, to be first employed in the second stage of the development of syphilis, in the third to fourth month from its commencement.

Agreeably to our present knowledge, the choice must lie between preparations of mercury and iodine. These are now employed in a very different fashion from of old. The therapeutics of syphilis depend more than any other group of diseases on clinical observation, for experiments on animals have resulted, in its case, in little instruction in pathology and pharmacodynamics.

Mercury is to be regarded as the direct, iodine as the indirect, remedy for syphilis. As is well known, one can obtain the removal of its manifestations by the outward application of very simple preparations of the first, and simultaneously can favor the formation and growth of normal tissues. What we so frequently observe with regard to syphilitic products in structures patent to the eye goes on, without doubt, in those lying deeper, especially in the tracts of lymph and blood-vessels. The carriers of syphilis, "the white corpuscles," are destroyed and excreted, healthy red ones become more numerous, and nutrition in general improves. The clinician can so indubitably establish this with respect to the most varied forms of syphilitic products, that a different verdict can only be ascribed,

if expressed, to a defective way of using the remedies; it being distinctly understood that with the medicines all indicated aids to the removal of the disease are to be sedulously employed.

Iodine favors absorption both in and by means of the lymph vessels, and is thus the most powerful remedy in scrofulosis and in rheumatic and gouty dyscrasiæ. It eases the pain like a narcotic; it hinders inflammation and favors sleep; finally, it promotes the excretion of certain metals from the organism, as of mercury. Hence it is remarkably curative when used against the results of its misuse. Its internal exhibition does not permit the conclusion that the syphilitic virus is destroyed by iodine, but merely that the unburdening of the lymph and blood from the elements of the scrofulous, rheumatic, and gouty dyscrasiæ, as from mercury, makes more free the natural tendency of the organism towards recovery, and with this forwards its co-operation for the removal, or at least amelioration, of the syphilitic manifestations. Iodine exerts a plainly rapid influence on the gummata in cases where a complication, in general the scrofulous, exists. This, frequently long latent, is first evoked, even in those apparently robust, by syphilis.

The sedative influence of bromine on the nerve centres, particularly the cerebral, those of the heart, and sexual apparatus, makes it a useful auxiliary in the treatment of the syphilitic, although itself possessing no direct power over the dyscrasia.

Mild forms of syphilis disappear under the use of pilocarpine subcutaneously more rapidly than when treated by the expectant method, and severer improve. By its use alone, however, we do not obtain permanent cures, while its continued employment in increasing doses acts unfavorably on the health of the patient.

In the contest between mercurialists and anti-mercurialists which has been waged for four hundred years, were humanity and knowledge alone the motives in such a dispute, the public, the patient, and the medical man (too often difficultly placed as regards the latter) would all be gainers.—*Edin. Med. Journ.*, Jan., 1882.

ABSORPTION OF VIRUS FROM THE SURFACE OF WOUNDS.—At the meeting of the Académie des Sciences on December 22, 1881, M. DAVAINE read an interesting article on this important subject. Any exact knowledge as to the time in which cauterization must be practised to prevent absorption cannot but be of great value, as one may well hesitate to cause useless suffering by a tardy cauterization, or to expose the patient by a too prolonged expective treatment to the dangers of infection. The experiments of Renault on the poison of glanders, and those of Colin on anthrax, demonstrated that absorption from a subcutaneous punctured wound is extremely rapid, and that cauterization was useless when performed later than ten or twenty minutes after inoculation. M. Davaine, however, shows that certain characters of the wound may serve to delay the rapidity of absorption. Having placed material from a case of anthrax on the surface of wounds produced in rabbits by vesicants, friction with rough surfaces, or the removal of a small piece of skin, he found that many animals survived when the wound was cauterized with caustic potassa one, two, or even three hours afterwards. M. Davaine suggests as an anatomical explanation that in a sub-epidermic wound a number of small vessels are divided and the circulation is maintained by the collateral branches which are given off immediately below the divided vessel, and by this the poison, which has penetrated into the interior of a wounded vessel, reaches the general circulation. In a more extensive wound even the collateral branches will be largely destroyed and this direct entrance of the poison into the circulation will be retarded. Therefore, even though punctured wounds are the most dangerous, it seems prudent to cauterize infected wounds even if several hours have passed from the time that they were inflicted.

It may be noticed that the above results do not deal with the wounds inflicted by bites, although they apply closely to wounds such as a surgeon would be apt to inflict on himself with a knife. No allusion is made to the use of the hot iron, the cautery which would naturally suggest itself, M. Davaine having only made use of sulphuric acid and Vienna paste. It is to be hoped that this line of research will be extended.—*Gaz. Méd. de Paris*, Dec. 24, 1881.

CURE OF DEAF-MUTISM.—Two cases of deaf-mutism observed in young children, who recovered their hearing sufficiently for them to learn to talk, furnished M. BOUCHERON with the subject of a memoir, which he read at the meeting of the Société de Médecine de Paris, on October 8, 1881. The first case was in a child two and a half years old; the second, four and a half years old; both had strong constitutions and quick intelligence, never having had convulsions, and of healthy parents. In the first case M. Boucheron diagnosed pharyngeal catarrh, propagated by the Eustachian tube to the tympanum, the tube, later, being obliterated by the swelling of its mucous membrane. After one year the child was able to hear loud talking, and was able to pronounce very distinctly the words which it learned without paying any attention to the movements of the lips. The diagnosis was the same in the second case, who partially recovered hearing in a month, and after five months was able to pronounce the words which were heard. M. Boucheron compared the mechanism in the case of these deaf-mutes by compression of the auditory nerve to blindness produced by compression of the optic nerve in glaucoma, and proposed to designate the process by the term *otopiesis*. He thinks that this idea will suggest the line of treatment to be recommended, viz., the inflation of the tympanum by a catheter introduced during anæsthesia and the reduction of the pharyngeal inflammation by astringents.—*L' Union Méd.*, Dec. 25, 1881.

PALLIATIVE TREATMENT OF ATRESIA VAGINÆ.—Dr. A. F. ERICH reports a case of atresia vaginæ where an operation was positively refused. Menstrual molimina occurred at the age of fifteen. The abdomen began to enlarge, and she suffered intensely at every menstrual period, requiring large doses of morphia to control the pain. She had been under Dr. Erich's treatment for three years now, and requires no morphia at all. About a week before the beginning of the menstrual period she begins taking half-drachm doses of potassium bromide, three times a day. This reduces the hyperæmia, and so limits the amount of blood thrown out during menstruation. In the inter-menstrual period so much of the fluid portion of the blood is absorbed as to keep the tumor from enlarging, or slightly to decrease its size. She suffers at her menstrual periods no more than many women who consider themselves perfectly well. Dr. Erich suggests the further testing of this treatment in such cases.—*Atlanta Med. Register*, Nov., 1881.

LOSS OF SIGHT IN YELLOW FEVER.—In the *Archives of Ophthalmology*, for December, 1881, Dr. JUAN SANTOS FERNANDEZ reports three cases in which there was complete amaurosis in the course of yellow fever; in the only case in which an ophthalmoscopic examination was made, no abnormal condition was detected. He was also able to confirm the external changes known to occur in the cornea and conjunctiva, but the existence of amaurosis, which may be only temporary, has not been before reported.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, FEBRUARY 4, 1882.

PREVENTION OF CONTAGIOUS DISEASES.

GRADUALLY but steadily the conviction has been gaining ground that diphtheria, like scarlet-fever and similar diseases, is communicable from person to person, either directly as, for example, in the notable case of a member of one of the royal families of Europe; or through the medium of the air, or of various substances which have come in contact with the products of the disease. Instances have been cited which seem to indicate that milk has sometimes been the vehicle of introducing the poison into the system.

The fact of the contagiousness of this disease, however well established it may appear to be to the medical profession, is not sufficiently well understood by the general public, especially in its relations to the employment of the proper means of prophylaxis. Hence, one of the chief causes of failure in the successful application of measures designed for modifying, checking, or preventing the progress of epidemics of infectious diseases, is the want of the intelligent co-operation of the public, springing mainly from ignorance of the nature of these affections, their mode of propagation, and particularly of the course to pursue to prevent their spread. Every medical officer of health will corroborate this statement by his experience in numberless cases where the grossest ignorance of the plainest sanitary preventive measures has well-nigh thwarted his best-directed efforts to protect the public health. The experience of every physician bears evidence in the same direction.

It must be admitted that without plainly instructing the people in relation to the preventive management of contagious diseases, and, as inseparably connected therewith, in their duties to themselves, their families, and to the public, satisfactory progress cannot be expected in the work of restricting and intercepting the propagation of these affections, which, though in a great measure preventable, are constantly making their presence seriously felt in every community. Sanitary laws and ordinances are eminently proper and absolutely necessary, but though well conceived in the first place, and well understood by the sanitary authorities, they fail or are only partially effective in their application, unless the people are made familiar with their meaning and objects, and are instructed by plain rules in their obligations and duties.

As a medium of imparting this information, physicians hold no secondary position, and in this relation sustain a very weighty responsibility to society. Their early information of the case—almost invariably in advance of that obtained by the health officer—affords an occasion and advantage of vital importance for promptly instituting decisive measures. Even when there exists only a suspicion as to the nature of the disease, which may scarcely justify a report to the proper authorities, the exercise of the utmost caution and foresight will not be unproductive of good, especially should the subsequent development of the case confirm this suspicion. Their opportunities for directing and controlling the proper protective measures are at all times specially prominent. Their relations to the family enable them to exert a more than ordinary influence in this sphere of action. Their co-operation with the health authorities is of the greatest value in their efforts to compel observance of the salutary provisions of the health ordinances. The physician cannot divest himself of this additional and weighty responsibility, and the more fully he realizes it, the better fitted will he be to discharge the duties of his high office.

However valuable and indispensable the services of the medical profession, either in the capacity of medical advisers or as private citizens, may be in the dissemination of useful information upon important sanitary topics, there is still great need of a more general, comprehensive, and systematic means of educating the masses of population in this special knowledge, particularly in respect to the requirements of preventive medicine. Plain, systematic, authoritative instruction in the details of the management of contagious cases, should be imparted to every responsible member of the community, and this should emanate from the board of health or sanitary council. There is no better or more suitable method of carrying out this aim than by the use of circulars, describing in plain and unmistakable language the chief features of domestic sanitation and

its relations to public health, and the precautions necessary to observe in all diseases dangerous to the community. These circulars should have the widest distribution, and should form the invariable guide when cases of disease occur. Several American local and State boards of health—notably that of Michigan—have adopted this plan, in several instances, with fruitful results; but the method is capable of more general application than it has yet received, and, happily for the future, this conclusion is beginning to be more fully realized.

These tracts would be specially valuable in the hands of the physician, as they could either take the place of or supplement his advice, and being authoritative would be more likely to command observance, especially after they had received his endorsement. Their convenience, where it may be difficult to communicate verbally all the details of management affecting the family and society understandingly, is at once apparent; so, likewise, in cases where there is intelligence and willingness, but where all the minutiæ have not been explained or comprehended, and therefore have failed to be carried into operation.

But the prominent object is to instruct the public—not simply those employed immediately about and associated with the sick—so that they shall at all times be prepared for any emergency, and be able to judge intelligently of the proper course to pursue. It is also to foster a healthy popular sentiment against the infringement of sanitary protective law, based upon a clear conception of its meaning and importance. Books of a class of which the Health Primers are a type are exerting a good influence in this same direction, by disseminating sound, practical information on subjects that so intimately concern the public. The American Public Health Association is another valuable agency for spreading knowledge upon important sanitary topics. Through its members, who are now located in every part of the country, an impetus could and should be given to domestic sanitation in its various branches. Journals devoted solely or in part to the subject of public health are also an efficient instrumentality for the diffusion of useful knowledge, and their prosperity is an evidence of the existence of a public want, and of an appreciation of the effort made to meet it. The capability and special fitness of the medical press for rendering a fruitful service in the sphere of public instruction is not lost sight of, and the appreciation of its high office and grand function of unfolding the laws and teaching the principles of hygiene—the prevention of diseases—first to the profession and through them to the multitudes, is evinced by the custom with every journal of repute of regularly devoting a considerable space to the presentation and discussion of this subject.

OUR NATIONAL MEDICAL MUSEUM AND LIBRARY AND THEIR DANGER.

THE Surgeon-General of the Army has sent to Congress, through the Secretary of War, a special estimate for $300,000 for the purchase of a site in Washington, and the erection thereon of a fire-proof building, to contain the Records, Library, and Museum of his Department. This estimate is accompanied by plans of the building proposed, which is recommended to be of brick, and to be a plain, substantial, thoroughly fire-proof building. The estimate and plans are now before the Committees on Public Buildings and Grounds, in the House and Senate respectively, and it is highly desirable that these committees shall be informed of the opinions of those competent to judge as to the value of these collections and the necessity for a new building in which to store and arrange them so as to secure their preservation and greatest utility.

As to the value of the collections there cannot be a shadow of doubt; they are of national importance, and their value to medical writers and teachers, to those interested in sanitary matters, to medico-legal experts, and to scientific men of all branches cannot be estimated in money.

The library is the largest, and in every way the most valuable, of any collection of its kind in the world. The Museum contains 22,000 specimens, and is unique in the completeness with which it illustrates military surgery and the diseases of armies.

The Records consist of over 16,000 bound volumes of manuscript hospital records with a large mass of papers, including the medical records of our late war. The propriety of a reasonable expenditure on the part of the Government to secure the permanent preservation of these treasures and to make them accessible to those who wish to consult them surely requires no argument. And although the medical profession is especially interested in this matter, every man who is interested in the progress of medicine and the skill of physicians (and who is not?) should be equally interested.

These records, books, and specimens, are now contained in a building which is not fire-proof—which is unsafe as to its mere stability—which is insufficient not only for their proper arrangement, but even for satisfactory storage. It is surrounded by houses and sheds which are very inflammable and which are in immediate contact with its wings. The danger from fire is really a very serious and urgent one.

The accommodations for the officers and clerks are so limited as to cause serious inconvenience, and it needs but half an hour's inspection to convince any one that relief should be given as soon as possible.

We give elsewhere a list of the members of the committees on Public Buildings and Grounds, both for the House and the Senate, and we strongly advise those of our readers who have the personal acquaintance of any of these gentlemen to write to them at once and tell them what is thought about this matter.

More than this, we advise those who know any Senator or Member of Congress to take an early occasion to express their views on this subject and urge that the necessary legislation be passed to permit of the commencement of work during the coming summer. In this matter delays are dangerous.

RESECTION OF THE LUNG.

IN the MEDICAL NEWS for January 7, 1882, we called attention to the improvement in the method of treatment of localized pulmonary cavities by injection and drainage. We now find that attempts to extend this principle of surgical interference have been carried to the greatest length, as is seen in the number of attempts which have recently been made in Germany and France to demonstrate the possibility of partial excision of the lung without a necessarily fatal result. Dr. BLOCK and Dr. SCHMID, in the *Deutsche Med. Wochen.* for November 19, 1881; Dr. GLUCK, in the same journal for December 3, 1881; and M. MARCUS, in the *Gazette Méd. de Paris*, December 3, 1881, each report several instances in which they succeeded in removing portions of the lung in dogs and rabbits, the animals recovering from the operation, and in one case living as long as a year without apparent inconvenience from the mutilation. Schmid, indeed, reports one case in which he first excised successfully a portion of the right lung, and then six weeks later of the left; and he states that he intends to remove an entire lobe from the same dog in order to determine whether adhesions will increase the difficulty of the operation. Dr. Gluck, after satisfying himself of the feasibility of partial excision, and of the fact that ligation of the root of one lung did not necessarily produce fatal œdema of the other, attempted the removal of an entire lung in six dogs and fourteen rabbits. Of these, all but two died of pleuropericarditis, with fibrinous exudation. Two rabbits, however, survived without having shown any febrile reaction, only a transitory dyspnœa and no pulmonary œdema; and three months after the operation they were apparently in perfect health.

Dr. Block, who also, after numerous attempts, succeeded in a partial excision of the lung, states that the portion of the lung remaining expands sufficiently to fill the space occupied previously by the part removed, and that in successful cases no defect in respiratory murmur can be distinguished anywhere over the chest. He believes that this operation is destined to be generally performed in the majority of phthisical cases, gangrene of the lung, etc., as by it the patients not only are freed from the diseased organ, but receive a new, healthy lung in its place.

While these experiments may show that surgical interference with pulmonary disease is not so far removed from feasibility as generally supposed, and that pulmonary herniæ may perhaps with safety be excised, we can hardly conceive of any one foolhardy enough to act on the suggestion of Dr. Block and attempt the excision of a tubercular pulmonary apex.

VACCINATION.

THERE is no graver responsibility resting upon the medical profession than that which is involved in the question of vaccination. After a long and successful reign, the belief is again being fully investigated, both by the public and the profession, is vaccination as fully protective against small-pox as it was once thought to be? The question admits of an easy and most decided answer—that there exists no particle of evidence that a recent properly performed vaccination is in any degree less of a safeguard against variola than it has always been claimed to be. If this dogmatic assertion is true, and it cannot successfully be assailed, it is incumbent upon us to account for the fact that cases of variola have been observed in the persons of those who have been recently vaccinated. But this fact will present no difficulty to those who have observed the carelessness with which the operation has been done, and the character of the virus used in many cases.

The occurrence of an almost infinitely minute proportion of cases in which syphilis has been said to be conveyed by vaccination, has led to a most unfounded prejudice against humanized virus, and has made its employment often impossible, although most excellent authorities, and some of them those possessing the largest experience, rely upon it to the exclusion of all other, as more regular, more rapid in its course, and equally efficient.

It is just here that the duty of the profession to the public is afforded a most important field to labor in. Where from prejudice, fashion, or any other reason it is necessary to resort to bovine virus, if the same caution is used in the selection of that virus as is bestowed upon that of a crust from the human arm, quite as efficient protection will attend the performance of the operation.

The pedigree of the virus, that of the animals from which it was procured, and upon which it is propagated, and the amount of dilution to which it is subjected before being placed in the market, are all points which should receive the closest attention. Indeed, our representative medical societies can do

no better work than to carefully examine and report upon the system pursued, and the painstaking care bestowed upon the business, in the numerous "vaccine farms" which so loudly claim the patronage and endorsement of the profession.

Upon individual members of the profession rests the responsibility of so carefully performing the operation, and so critically scanning its results, that the public will cease to regard it as a simple mechanical procedure which can be successfully practised by any one who becomes possessed of a "point." When the same conscientious care is bestowed upon vaccination, as was formerly done by our predecessors, we may expect to see the same efficiency in its results, and the public will be ready to recognize its value by a suitable honorarium.

When vaccination is carefully performed, and practitioners refuse to recognize any case as being successfully revaccinated until certain specific results are obtained, altogether independent of the question of soreness, we shall cease to hear of variola appearing after a recent vaccination.

One of the chief objections encountered by the advocates of compulsory vaccination, and, indeed, almost the only cause for opposition to it among educated people, is the possibility of the transmission of syphilis by its means. As animal lymph has been shown to have equal protective power with the humanized lymph, and as horned cattle are known, on the authority of MM. Depaul and Ricord, not to be liable to syphilis, this obstacle was largely removed, but now the question of the possible communication of other diseases from cattle to man is being raised. We are told, however, by Dr. Dompeling, the director of the Utrecht vaccination station, that veterinarians in Europe are of the opinion that the diseases of calves and heifers are, on the one hand, not transmissible, and on the other, have such distinctive characters as to be easily recognized and avoided. Dr. Creighton, of Cambridge, is, however, convinced from numerous experiments that it is possible to propagate tubercle from one species to another, and, although his views are combatted by such authorities as Drs. Günther, Thudicum, Carpenter, and others, he yet undoubtedly brings forward strong presumptive evidences of the truth of his statements. At Utrecht the *parc vaccinogène*, or "vaccine farm," is an annex of the veterinary school, and Mr. Ernest Hart, who opened the discussion on this subject at the late meeting of the British Medical Association, is of the opinion that to render precaution complete, it would be serviceable to have a veterinary surgeon attached to every such institution, thus ensuring the genuineness of the lymph, and its freedom from noxious qualities.

DARWINISM IN MEDICAL APPOINTMENTS.

THE doctrine of heredity is one of the most interesting offshoots of the Darwinian speculations, and is capable, when it shall be thoroughly investigated by accurate observers, of throwing much light on many obscure points in the social organization, as well as in the animal world. It is true that in its applications to dynastic succession the result has not always been happy, according to current historical beliefs. Still, this may be owing to the prejudices of partial or mendacious chroniclers, and further investigation may show the current notions to be erroneous, as in the case of Henry VIII., whom Mr. Froude has demonstrated to have been a model husband, or of Lucrezia Borgia, whom a learned German has proved to have been a pattern of all womanly virtues.

Our attention has recently been called to a new development of the truths of heredity, quite as convincing as the fact that the domesticated dog will always turn round once before lying down establishes his descent from the wild animal, which was obliged to take this precaution to insure that his rest would not be rudely disturbed. For the benefit of science, therefore, we are glad to be able to announce the generalization from the isolated observations of several very wise governing boards, that the qualities which render a man well fitted for the duties of a medical teacher or of a hospital physician, and acquire for him just reputation, are transmissible to his offspring. Even the experience which is requisite to the safety of the indigent sick, who seek the hospital bed as a last resort in the struggle for life, comes by inheritance, as well as the faculty for imparting instruction on which the student depends for his success in the profession, on which he has staked his career.

Any one who may entertain the old-fashioned notion that an appointment to a professorship or to a hospital position should be a recognition of professional eminence or of ascertained fitness should hasten to clear his mind of such conservatism; it may now be fairly conceded that the theory is established that an applicant's claim to so important a position must no longer be based on aptitude, long training, experience, and reputation, but on his ancestors, since talent is hereditary and special characteristics are developed by the devotion of several generations to the same pursuit. By a judicious system of intermarriage it is believed that these hereditary excellences may be still further intensified. Indeed, there is no telling to what extraordinary official merit this fact of heredity may lead, or how widely its application may extend, if only the vulgar prejudice in favor of proved capacity can be excluded permanently from the minds of trustees and hospital managers.

We trust that no uncharitable observations by disappointed aspirants will be permitted to obscure the brilliancy of this useful addition to our store of scientific observation. Perhaps not the least of the subsidiary benefits which it will confer will be to release the boards of all our institutions from the harassing canvasses to which they have heretofore been subjected. When we recall the perplexing care with which a conscientious manager or trustee would weigh the qualifications of the several candidates, in order to discharge the very important duty involved in his trust, of selecting among numerous prominent and capable competitors the one best fitted to bear the tremendous responsibilities of the position, we recognize fully the relief which will hereafter be experienced when it is necessary only to ask if a man be the son of his father, without troublesome inquiries as to his age, color, or previous condition of servitude.

THE INFECTIOUS CAUSES OF INFLAMMATION.

WE ask attention with peculiar pleasure to the lectures of Cohnheim on the infective causes of inflammation, which appear in this, and the number of the NEWS for January 21. These lectures are furnished us by the courtesy of their author, and they will be embodied in the forthcoming new edition of his *Allgemeine Pathologie*. Our readers are, therefore, enabled to see these important observations in advance of their publication elsewhere. The existence of a *contagium vivum* is strongly supported. All infectious diseases originate from a parasitic organism. The observations of Koch on the life-history of the *bacillus anthracis*, threw a strong light on the nature of these bodies, and on their mode of reproduction. Prof. Cohnheim maintains the view that there is a special organism for each form of infective inflammation, and he traces the changes in the walls of the vessels to *schizomycetes*. But our readers will, we doubt not, read these lectures of the master, and hence we proceed no further in our analysis of them.

HIDING SMALL-POX.

THE recent action of the Philadelphia Board of Health in censuring a homœopathic practitioner of medicine for not duly reporting a case of small-pox, calls attention to the startling dangers that attend every case unless the utmost care is taken to prevent the spread of the disease. It is stated that in this case there was a funeral attended by forty or fifty persons and that neither the clergyman who conducted the services, nor the friends who were present were informed of the nature of the disease. None of these persons took, therefore, any precautions against it. The friends and servants who nursed and attended the patient, were kept in ignorance of the true nature of her disease. One of the latter, who had not been revaccinated, contracted the small-pox. Her case was promptly reported to the Board of Health by a regular physician who was called in to attend her, and the arrival of the ambulance to convey her to the small-pox hospital, where she subsequently died, was the first intimation that the boarders had of the existence of the disease in their midst.

Subsequently, when the true nature of the disease became known, at least one large school was closed because some of the teachers had been unknowingly exposed to the disease as boarders in the house in which the cases occurred.

It is not made the legal duty of the physician, under the rules of the Board of Health, to inform the occupants of a boarding-house of any case of small-pox which may break out in it nor to see that they are vaccinated, but surely, both from a prophylactic and a moral standpoint, it is his duty to do so, whatever may be the detriment to the mistress of the house or the inconvenience to the boarders.

We know also that not a few physicians neglect to report contagious diseases, other than small-pox, in spite of the positive legal obligations to do so, and we direct attention anew to the law for the purpose of urging obedience to its just requirements.

The addition to the later blanks in red ink at the foot requiring the physician to report whether he has forbidden the children of the family to attend school or other places of public resort is also a matter of prime importance, especially at this time.

It is high time also that, by law, funerals in all cases of contagious disease be made private, and published notice be given of the cause of death.

The reports just received from Mt. Carmel and Gratz, given in another column, afford additional evidence, if it be needed, of the necessity of stringent laws and their strict enforcement, for the prevention of the spread of contagious diseases.

REVIEWS.

DIE FUNKTION DER BOGENGÄNGE DES OHRLABYRINTHS. Von Dr. BENNO BAGINSKI. Berlin: Pamphlet, pp. 9.
THE FUNCTION OF THE SEMICIRCULAR CANALS. By Dr. BENNO BAGINSKI.

The obscurity associated with Menières disease from a pathological point of view renders any facts relating to the functions of the semicircular canals of the greatest interest. Among the numerous theories proposed to explain the mode of production of the peculiar movements which follow mutilation of these organs, there is probably none which has been demonstrated with any degree of certainty. The theory which has been most generally accepted is that disturbances in the pressure of the endolymph are accountable, and an experiment of Munk of increasing the tympanitic pressure, and consequently the labyrinthine pressure, by injecting fluid into the tympanum is often quoted in its support. Dr.

Baginski has, however, found that these effects are only produced when the pressure is increased sufficiently to rupture the membrane of the round window, by which means the fluid is permitted to penetrate to the brain through the communication of the aqueductus cochleæ with the scala tympani, and the latter with the sub-meningeal space. In all cases where the movements followed, it was found that inflammation or hæmorrhage was produced in the neighboring parts of the brain, and that the rapidity with which the symptoms appeared, and their severity, was proportionate to the irritating qualities of, and pressure exerted by, the injected fluid.

It will be recollected that irritation of the portion of the corpus restiforme, which lies immediately under the jugular fossa, has been found by Magendie, Schiff, and others, to cause analogous results, and Dr. Baginski points out that in both cases we probably have a similar mechanism, with the addition, in the case of the injections, of a labyrinthine irritation. To eliminate the value of the latter, Dr. Baginski employed the method of Heidenhain of removing a portion of the bulla ossea by which the canals are directly reached, and he found that dogs in whom portions of the bony labyrinth are removed became perfectly deaf, but showed no disturbances of equilibrium when the brain remained uninjured, even though the entire labyrinth underwent fatty degeneration. When, on the other hand, an entire semicircular canal was removed then the disturbance appeared, but could be directly traced to an inflammatory condition of the brain.

The author shows that a similar mechanism explains the losses of equilibrium in birds after injury of the canals, and denies there being any relationship between the location or direction of the canal injured and the character of the resultant motion. He concludes that whatever may be the function of the labyrinth, it is not for the purpose of serving "an equilibrium sense," and it is probable that the gross lesions of the semicircular canals in the rare cases of Menières disease, which have been carefully studied, have been associated with less evident lesions of the adjoining parts of the brain.

CORRESPONDENCE.

HYPERMETROPIA IN THE PUBLIC-SCHOOL CHILDREN.

To the Editor of the MEDICAL NEWS:

SIR: The correspondence columns of your last issue, page 113, contain a communication from Dr. Loring, of New York, criticising the report of Dr. Risley "On Weak Eyes in the Public Schools of Philadelphia." Taking hold of the loose statement as to "*all foreign statistics*," the writer endeavors to show that the percentage of hypermetropia found by foreign observers is in close accord with his own investigations, which he seems to think have been assailed: and he thus tries not only to convict Dr. Risley of great inaccuracy in his quotation, but also to throw doubt on the value of his entire work. By the sweeping "*all*" thus inadvisedly used, were evidently meant all which were in any way comparable in extent and thoroughness. As to this, Dr. Loring himself says as introductory to his own statistics (*Trans. International Medical Congress, Philadelphia*, 1876, p. 929): "I choose these" (Erismann's and Conrad's) "as examples, since they are the only ones which I know of where sufficient numbers were used, and where at the same time the conditions of investigation were the same, or nearly the same, in each. Thus they are all upon the eyes of school children between the ages of six and twenty-one years, and the trial-glasses and Snellen's type at twenty feet were the basis of examination."

The array of authorities which he cites would generally seem, at first glance, to bear him out most completely in his criticism; but an examination of the table in which Emmert summarizes these same results (and from which Dr. Loring seems to have taken his table), shows several important facts. Cohn, Erismann, Hoffmann, Gayat, Conrad, and Pflüger, are the only ones of the fifteen whose figures reach one thousand scholars. Of Cohn's work, Dr. Loring has said (*loc. cit.*) "but unfortunately Cohn's statistics, extensive as they are, are not suitable for our purpose; since from the manner in which they were compiled, no correct idea can be obtained from them of the frequency with which, in comparison to each other, the three different classes of refraction occur." Were this all as to Cohn's figures, they might pass; but while Dr. Loring quotes his two studies giving percentages of 2.3 per cent. and 7 per cent. respectively, he omits his examination *under atropia*, where the percentage of hypermetropia was *over 88 per cent.*—an omission no doubt accidental.

Gayat, among 1588 pupils, found hypermetropia *manifest* among only 6.8 per cent. Conrad, whose statistics Dr. Risley excepted through a mistake, found with the ophthalmoscope 70 per cent. of hypermetropes among the children of six and eight years of age, while his lowest figures were 23 per cent., and the average among his 1518 scholars must be above 50 per cent. (the full figures are not at hand). Yet Conrad's percentage is quoted by Dr. Loring at 11.76 per cent.—his showing in reality of the manifest, not the total hypermetropia, which Dr. Risley has evidently sought. Erismann and Pflüger, whose 6206 scholars make up more than half of the list Dr. Loring cites (Cohn omitted), give 43.3 per cent. and 44 per cent. respectively; while Emmert, whose figures are entirely ignored, although his summary of the work of others has apparently been employed, found among 2148 scholars 77 per cent. of hypermetropes.

The other investigators of Dr. Loring's list examined numbers of pupils varying from 122 to 800; yet the percentages thus obtained, and representing in almost all cases only the hypermetropia manifest revealed by the test of trial-glasses, Dr. Loring puts on the same footing as that derived from Erismann's 4300 pupils—a proceeding manifestly too unjust to need further comment.

Summing up the work of those whom Dr. Loring cites, excluding Cohn (and many others would be as rightly excluded for the reasons above given by Dr. Loring himself), and adding the work of Emmert, we find that 14,622 scholars in the various schools, gymnasia, and universities, were examined, and 5094, or 28.7 per cent. of them found to be hypermetropic—just double the figures given by Dr. Loring. Remembering the fact set forth by Dr. Risley and many others, that the test by trial-glasses and Snellen's type at twenty feet is quite inadequate to show more than a fraction of the total hypermetropia (Conrad found by the glasses only 16 per cent., and 70 per cent. by the ophthalmoscope, at eight years), and that only in a few of the examinations was this latter means employed at all—we have the fullest corroboration of Dr. Risley's results.

To cite a few examples: Cohn among 240 pupils *under atropia* found hypermetropia in more than 88 per cent.; Emmert among 1884 eyes of pupils between the ages of ten and thirteen, inclusive, found 80.6 per cent. hypermetropic. Erismann among the 59 pupils of his lowest grade found 67 per cent. hypermetropic and 55 per cent. among the 783 of his second; while Dr. Roosa, quoting his paper, says, "Erismann states that under atropia it is probable that there would be a larger percentage of hypermetropia than he found, and

that the hyperopic eye is probably the normal one in youth." (*Trans. Am. Ophthal. Soc.*, Vol. ii., p. 385). Compare these with Dr. Risley's figures and his 74 per cent. does not, at all events, stand alone; while a hasty study of the methods of examination employed in other published investigations, fails to show that anywhere the same thoroughness and precaution were used, Dr. Loring to the contrary notwithstanding. It may be that the proportion of hypermetropic children in the schools of New York City does not exceed an average of 13 per cent.; but I fear that any remark from an outsider as to the New Yorker's lack of far-sightedness would rouse an indignant rejoinder.

In the preparation of this hasty communication only a few of the publications involved have been attainable, and many quotations at second-hand have been therefore necessary; yet I believe it will throw a truer light on the subject than did the letter which called it forth.

Very respectfully yours,

B. ALEX. RANDALL, M.D.

1835 CHESTNUT ST., January 31, 1882.

NEWS ITEMS.

CINCINNATI.

(*From our Special Correspondent.*)

FREE VACCINATION at the Health Office has been suspended by the health board. Gratuitous vaccination, it was at first supposed, would be accepted only by the very needy of the city. But it was soon discovered that among the hundreds who daily applied were very many who were well able to pay for their attendance, as well as others who came from neighboring villages. The work has now been transferred to the district physicians in the different wards of the city, they being less likely to be imposed upon by non-residents and those in good pecuniary circumstances.

SPRING SESSIONS will be held this year, as usual, by the three regular medical colleges. These will begin about the middle of March and continue two months. They are designed principally as post-graduate sessions, and consist mainly of clinical, laboratory, and operative courses. These are not recognized by the colleges as regular lecture courses, such as are demanded of the candidate for the degree.

Summer graduating terms are here looked upon with disfavor, and are considered mere catch-penny affairs, and none of our colleges hold such sessions.

PITTSBURG.

(*From our Special Correspondent.*)

ARRESTS FOR ADVERTISING NOSTRUMS.—Through the efforts of Drs. Jos. N. Dickson, Wm. R. Hamilton, and one or two other physicians in this city, there has been, within the last ten days, several arrests and convictions of irregular practitioners and one druggist for "advertising medicines, drugs, and nostrums for the cure of secret diseases, etc."[1]

There are suits pending against Dr. Hartman and others who have escaped from the city and State. Dr. C. R. Lightner (a graduate of Bellevue Hospital Medical College) was arrested and convicted for advertising (in common with his partner, Dr. Hartman,) Pe-Ru-Na, which, it is stated, among many other things, will "restore sexual debility to the energy, fire, and vigor of youth." After conviction, Lightner was let off upon payment of all the costs and attorneys' fees, and his voluntary publication of a card in the daily papers, promising "not to distribute pamphlets recommending nostrums, etc., for private diseases and female complaints."

Another man was convicted for advertising "Ricord's Specific Pills" for gonorrhœa, gleet, and similar diseases. He is a druggist here, and an ex-president of the College of Pharmacy. He took high ground when arrested, and asserted he was being prosecuted for purposes of blackmail, but changed his tune when he discovered it was impossible to make any settlement of the case that would at all benefit the prosecutors in any way. To mend his ways and sin against public decency no more was the only ground upon which he could be let off. He, likewise, made solemn promises, and published a card, stating that until recently he was ignorant of the law touching advertisements of certain patent medicines and nostrums, and that since he has been informed of the law on the subject, he has withdrawn his advertisements, and he declares his intention to comply with the law.

Dr. George was arrested for a like offence, and lodged in jail in default of bail. He plead guilty, paid his fine on two charges, and promised to do better in future.

[1] *Vide* Pamphlet Laws of Penna., 16th March, 1870, forbidding publication of nostrums for secret diseases, etc.

SCOTLAND.

(*From our Special Correspondent.*)

ABERDEEN UNIVERSITY.—Sir Erasmus Wilson has just added to his munificent benefactions to science the gift of £10,000 for the institution and endowment of a chair of pathology in the University of Aberdeen. The professional staff of this medical school has long felt the want of pathological teaching, although, with the exception of Edinburgh, no other university in Scotland is provided with a chair for this subject.

UNIVERSITY OF EDINBURGH.—At present the degrees of Bachelor of Medicine (M.B.) and Master of Surgery (C.M.) are granted jointly or separately, after precisely the same examinations. Nearly all medical graduates have been accustomed to take both degrees, as two separate qualifications, one in medicine, and the other in surgery, are requisite for entrance to the army and navy, and for other public situations, although in point of fact the taking of the one implied the possession of the knowledge requisite for the other, and, if the extra fee were paid, the actual possession of the other degree. By recent powers obtained from the Privy Council, the Senate of the University has resolved for the future to grant the degrees always jointly, so that it will be no longer possible for any student to obtain the one degree without the other.

SMALL-POX.—The mortality returns for the week ending January 28, give the following number of deaths from small-pox. New York, 11; Philadelphia, 18; Boston, 6; Erie, Pa., 1; Richmond, Va., 21; Wilmington, Del., 1; Gould, Kan., 6.

The returns to the National Board of Health during the same period show 6 new cases at Dayton; 3 at Indianapolis; 2 at Winchester, Va.; 3 at Louisville; 16 at Gould, Kan. At Cincinnati 22 new cases were reported on the 28th, and 26 on the 30th. At Pittsburg 18, and at Allegheny 6 new cases were reported on January 31. During the month of January the mortality in Philadelphia, as compared with the same month of 1881, had diminished 60 per cent.

SMALL-POX IN MOUNT CARMEL, ILL.—Mount Carmel, Ill., has recently passed through an epidemic of small-pox which is interesting from the accuracy with which the starting-point of the epidemic was traced, and the marked character of the disease in the early cases. After exposure to the contagion of small-pox in St. Louis, where he roomed with a man who subsequently died in the pest-house of variola, a man aged

forty-eight years died suddenly in the cars while in the company of his daughter and some friends, and his death was not suspected until it was time to change cars. No eruption was found on his body with the exception of a discoloration said to resemble purpura, which existed on his body and thighs. No one was apparently aware of the fact that he had been exposed to small-pox. The funeral was largely attended. Fourteen persons were exposed to the disease in handling his body, of whom twelve had been vaccinated and two had not. Both these last died of small-pox. Of the former only one suffered, and he in a very light form, and recovered. Three others, unvaccinated and exposed in attending the first two, died of small-pox. Four others also had varioloid or small-pox and recovered. Three of them had been vaccinated; the fourth, who had not been, was an exceptionally strong and hearty man, to which, doubtless, he owes his escape. We are indebted to Dr. J. Schneck, Chairman of the Mt. Carmel Board of Health, for an admirable report of these cases, of which six died and five recovered. All of the ten cases could be traced to contact with the body in preparing it for burial, while ignorant of the cause of death.

SMALL-POX AT GRATZ, PA.—From a press dispatch of January 30, we learn that considerable excitement prevails at Gratz, a small town a few miles from Harrisburg, over the small-pox. Last week a prominent citizen died of small-pox, but the nature of the disease not being announced by the physician, there was an old-fashioned country funeral, at which hundreds of people were present. The sickness of three children followed, and of those at the funeral seventeen are now down with the disease.

HEALTH IN MICHIGAN.—For the week ending January 21, 1882, the reports indicate that tonsilitis, intermittent fever, membranous croup, and rheumatism have considerably increased, and scarlet fever, erysipelas, inflammation of the bowels, and cerebro-spinal meningitis have considerably decreased in area of prevalence.

Cases of small-pox were reported as follows: Twelve, at Leesburg, in Prairie Ronde Township, Kalamazoo Co.; six, at Geneva, Van Buren Co., (believed to have been brought from Chicago); seven (convalescent), at Bay City; two (new), at Grand Rapids; two, at Detroit; one (a tramp from Grand Rapids), at Marshall; one (new), at Monroe; one also in Menominee Co., and one at Escanabo, Delta Co.

NEW YORK STATE MEDICAL SOCIETY will hold its annual meeting at Albany, February 7, 8, and 9, under the Presidency of Dr. Abram Jacobi. Interesting papers have been promised by Drs. E. C. Seguin, E. R. Squibb, M. J. Roberts, W. C. Jarvis, Geo. H. Fox, D. B. St. John Roosa, E. Vanderpoel, L. Elsberg, D. Webster, L. D. Bulkley, T. G. Thomas, A. Flint, V. P. Gibney, S. Sexton, E. H. M. Sell, D. Lewis, of New York, W. W. Potter, of Buffalo, and Hailes, of Albany.

UNIVERSITY OF PENNSYLVANIA.—The ordinance conveying to the University a lot of ground in West Philadelphia was passed unanimously by Councils and approved by the Mayor on January 24. A preliminary injunction restraining the Mayor from signing the deed of transfer, was obtained by a local newspaper publisher, but on January 31, after a full argument, was dissolved by the Court. It is probable that the transfer will now be consummated, and that the University will enter into possession of a valuable addition to its landed property.

THE INTERNATIONAL MEDICAL CONGRESS OF 1884.—Acting under the powers delegated to them at the final meeting of the Congress, the Executive Committee of the late Congress addressed an invitation to Professors Hanover and Panum, Vice-presidents of the Congress, to arrange for holding the next International Congress, in 1884, in Copenhagen. This invitation has been promptly and cordially accepted, and the next International Congress will accordingly be held, in the year 1884, in Copenhagen.

MEDICAL SOCIETY OF THE COUNTY OF KINGS, N. Y.—At the annual meeting of this Society, held January 17, Dr. C. Jewett was elected President, Dr. Hopkins Vice-President, and Dr. Wyckoff Secretary.

QUARANTINE AGAINST PITTSBURG.—The State Board of Health of West Virginia has given notice of its establishment of quarantine against the city of Pittsburg, on account of the prevalence there of small-pox, and it has directed inspection to be made by its agents of all passengers, baggage, and freights coming into the State from that city.

A NEW PROFESSORSHIP IN THE PARIS FACULTY.—By a decree published on January 2, 1882, on the report of the Minister of Public Instruction, a Chair of Clinical Professor of Diseases of the Nervous System has been created in the Faculty of Medicine of Paris. By another decree of the same date, M. Charcot, Professor of Pathological Anatomy in the Faculty of Medicine of Paris has been transferred at his own request to this new Chair.

HARVARD UNIVERSITY.—A person desiring to give a fund for the medical education of women in the Harvard University, asked the President and Fellows whether such a fund would be accepted and used as designed. Majority and minority reports were submitted by the committee of the Board of Overseers in charge, and after a long discussion it was voted, eleven to six, to adopt the minority recommendation, which is to accept a fund, the income of which shall ultimately be used for the medical education of women.

MEDICAL PRACTITIONERS IN WEST VIRGINIA.—The State Board of Health has licensed eight hundred and forty-three practitioners in medicine and surgery in this State. Three licenses were issued during the past year to itinerant practitioners. It is stated that under the influence of the registration law quite a number of former practitioners are at present attending medical lectures to meet its requirements.

Among the diplomas offered for verification, were discovered a few of spurious character, which had either been directly bought, or obtained upon a nominal examination. These, of course, the Board rejected.

ANTISEPTIC METHODS.—In its review of the *Annus Medicus* the *Lancet* thus speaks of carbolic acid. Indeed, we may say that the day of carbolic acid is over, not so much because of its danger, as because we have found a substitute or substitutes for it as reliable but not so poisonous. Incalculable good, however, has been achieved by means of carbolic acid; it has been thoroughly efficient, as a rule harmless, easy of manipulation, cheap, and has rendered antiseptic surgery possible years before it otherwise would have been. Carbolic acid has not failed, but something better has been found. These substitutes are eucalyptol, iodoform, terebene, and resorcin. Mr. Lister uses eucalyptol gauze, and finds it quite reliable; iodoform has been used by him, but it is chiefly famous for the results obtained with it by Esmarch and his assistant Tilmanns. At present resorcin has not been much used in this country, but it promises well. Connected with this change is

the substitution of a dry-cotton dressing for the gauze used by Mr. Lister; Esmarch employs cotton impregnated with iodoform, and Gamgee has introduced pads of absorbent cotton rendered antiseptic by carbolic and salicylic acids. Both of these dressings appear to be fast gaining in popularity, and certainly possess some advantages over the gauze. The "spray" has been abandoned by many surgeons, and even Mr. Lister has spoken in qualified terms of its necessity; and had we to prophesy, instead of to record accomplished facts, we might venture to predict an early abandonment of this cumbrous addition to a surgeon's armamentarium. Catgut prepared with chromic acid and kangaroo tendons have been introduced as new forms of animal ligature. They both appear to be trustworthy; the chromic catgut is a great improvement upon the old catgut, and is, indeed, one of the most important improvements of Mr. Lister's treatment introduced in recent years.

COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO.—We have received a preliminary announcement of this institution, which proposes to commence its first regular session about the 1st of October, 1882. It is stated that a pupilage of at least four years, including a graded course of instruction, covering at least three full winter sessions will be compulsory. Examinations for the degree of Doctor of Medicine will be conducted by a committee of examiners who have no other connection with the College.

The Faculty is not yet announced. Dr. A. Reeves Jackson is President, and D. A. K. Steele, M.D., Secretary of the Board of Directors.

HYGIENE IN SPAIN.—Spain is becoming more and more active in its participation in hygienic questions. A Hygienic Society has recently been formed, and approved by the King, of which the controlling section is located in Madrid with branches in all the capitals of the provinces and principal towns in the kingdom. Each section is composed of active and corresponding members, while the central society has the right of nominating honorary and foreign corresponding members. All who take an interest in hygienic science are eligible for membership. Each section is subdivided into sub-sections on general hygiene, epidemiology, climatology and medical topography, hygienic and medical statistics, and sanitary police.—*Gaz. Méd. de Paris*, Dec. 24, 1881.

MASSACHUSETTS GENERAL HOSPITAL.—The will of Mary Pratt, of Watertown, Massachusetts, recently deceased, gives $20,000 to this medical charity.

DR. BILLING'S ADDRESS ON MEDICIAL LITERATURE, read at the International Medical Congress, has been translated into French, and is being published in *L'Union Médicale* for January.

DIED.—At Edinburgh, on January 27, SIR ROBERT CHRISTISON, Bart., M.D., F.R.S. Sir Robert Christison was born on July 18, 1797, and was educated at the University of Edinburgh, where he received the degree of M.D., in 1819, and afterwards studied toxicology under Orfila in Paris. Soon after his return from the Continent, in 1822, he was appointed Professor of Medical Jurisprudence in the University of Edinburgh, and ten years later was promoted to the Chair of Materia Medica. In 1866 he received the degree of D.C.L. from Oxford, and LL.D. from his own University in 1872; he was created a Baronet in 1871. He twice held the position of President of the Royal College of Physicians, Edinburgh, and at the time of his death was Physician in Ordinary to the Queen for Scotland. His *Treatise on Poisons* is recognized as the standard work on the subject.

— At the end of December, at the age of eighty-four, M. BRIERRE DE BOISMONT, the well-known alienist. Born in Paris on the 18th of October, 1797, M. Brierre de Boismont received the degree of Doctor of Medicine in 1825. In the same year he published his *Elements of Botany*, and a treatise on *Pellagrous Insanity in Italy*. Among his other publications may be mentioned his work on *Suicidal Mania* and on *Hallucinations*.

NOTES AND QUERIES.

CONGENITAL BRONCHOCELE—VICARIOUS MENSTRUATION.

To the Editor of the MEDICAL NEWS:

SIR: In your issue of January 21, under the head of "Notes and Queries," I see a communication from Dr. M. R. Morden, Adrian, Michigan, asking if there had ever been any record of congenital bronchocele? I attended a lady on the 20th of this month, who gave birth to a male child apparently healthy, but I have since been called to see it on account of the anxiety of the parents about an enlargement of the neck, which I failed to notice (in my hurry) on the day of her confinement, and cannot, of course, be positive that it was present then; but it is certainly a veritable bronchocele. Will probably let you hear more of it as it progresses.

I would like now to ask if you or any correspondent can refer me to the record of any cases of vicarious menstruation?

Yours truly,

J. T. GORDON.

CARLYLE, ILL., January 25, 1882.

[Cases of vicarious menstruation are every now and then recorded in the journals. Our correspondent will find references to a number of examples in Churchill on the *Diseases of Women*. The latest recorded cases that we recall are one in the *New York Medical Journal* for August, 1881, p. 180, in which the patient vomited a considerable quantity of blood every month, and two in the *American Journal of Otology*, for April, 1881, p. 133, in which the hæmorrhage was from the ear.—ED.]

NATIONAL MEDICAL MUSEUM AND LIBRARY BUILDING.

THE plans and estimates for a National Medical Museum and Library Building, at Washington, have been referred by Congress to the Joint Committee on Public Buildings and Grounds, consisting of Senators Edward H. Rollins, New Hampshire; Justin S. Morrill, Vermont; Angus Cameron, Wisconsin; Charles W. Jones, Florida; George G. Vest, Missouri; and Representatives William S. Shallenberger, Pennsylvania; J. H. Lewis, Illinois; M. E. Cults, Iowa; M. L. De Mothe, Indiana; J. A. Scranton, Pennsylvania; Nicholas Ford, Missouri; J. Hyatt Smith, New York; Philip Cook, Georgia; A. S. Hewitt, New York; J. W. Singleton, Illinois; H. A. Herbert, Alabama.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 24, TO JANUARY 30, 1882.

STERNBERG, GEO. M., *Major and Surgeon*.—Granted leave of absence for one month, and during his absence Surgeon J. C. Bailey to attend the sick at Point San Jose, Cal.—*S. O. 9, Military Division of the Pacific and Department of California, January 16, 1882.*

COMEGYS, E. T., *Captain and Assistant Surgeon*.—Now stationed at Columbus Barracks, Ohio, to report in person to the President of the Medical Examining Board, in session in New York City, for examination for promotion, and, upon completion of examination, to return to proper station.—*S. O. 19, A. G. O., January 25, 1882.*

BANISTER, J. M., *First Lieutenant and Assistant Surgeon*.—Fort Reno, Indian Territory. Granted leave of absence for one month.—*S. O. 18, Department of the Missouri, January 24, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

CARTWRIGHT LECTURES.

ON THE EXPERIMENTAL METHOD IN MEDICAL SCIENCE.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, February 7, 1882.

BY JOHN C. DALTON, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

LECTURE III.

NERVOUS DEGENERATIONS, AND THE THEORY OF SIR CHARLES BELL.

MR. PRESIDENT AND GENTLEMEN: It is now a little over forty years since the beginning of an investigation which has produced most important changes in the study of the nervous system. It relates to the alteration of structure taking place in nerves after they have been divided by a transverse section.

The manner in which attention was first directed to this point is as follows. It had long been known that when a nerve was cut at any point, the immediate effect was a suspension of its functional activity. If it were a motor nerve which had been divided, voluntary motion was abolished in the parts below; and if a sensitive nerve, there was loss of sensibility in the skin where it was distributed. But this interruption of the nervous activity was not always permanent. In some cases the power of motion or sensation would return in the affected parts; and the ends of the nerve were then found to be reunited by a cicatricial tissue, in which there were connecting nerve-fibres of new formation. This reunion of a divided nerve, and the mode in which its structure and functions were re-established, formed the subject of many laborious investigations.

The observations in question were mainly directed to the cicatrix between the ends of the divided nerve. This was naturally supposed to contain the key of the whole secret, and consequently received most of the attention given to the subject. But in 1839 Nasse[1] extended his examinations to the nerve-fibres at a lower level. He divided the sciatic nerve in frogs and rabbits; and, after waiting from two to five months, found that the fibres in the separated portion of the nerve had become altered in structure. They were of irregular form, granular, and semi-opaque. They often contained what seemed to be minute fat-globules from the degeneration of their myeline, and they appeared to undergo in this way a gradual atrophy. Nasse's observations were almost immediately followed by those of Gunther and Schön,[2] which were to the same effect. They were made on the divided sciatic nerve in rabbits from twelve hours to one year after the operation; they showed that a nerve, after a few days' separation from its nervous centre, loses its irritability, so that its galvanization will no longer produce contraction in the muscles below; and that this loss of irritability coincides in time with the granular degeneration of its fibres.

All these researches were connected with the question of the re-establishment or regeneration of the nervous continuity; and they did not extend for any great distance below the point of section. Thus far, whenever observers use the term "regeneration," as applied to divided nerves or nerve-fibres, they mean the formation of new connecting fibres in the cicatricial tissue. It was supposed that when this reunion took place, the altered fibres below were restored to their normal condition, and the nerve in this way enabled to resume its functions. The fact of degeneration was considered as of secondary consequence, as limited in extent, and often of temporary duration.

But ten years later the subject was taken up afresh by Augustus Waller, and was treated by him in a manner so original and so thorough that it at once assumed a character of the first importance. Waller began his professional life in England as a practitioner of medicine, but he had a strong taste for independent research, and, after being for a time Professor of Physiology in the medical school at Birmingham, he transferred his residence to the continent, where he remained for most of his subsequent life and where the greater part of his scientific work was accomplished. For the anatomical study of muscular and nervous fibres he employed the tongue of the living frog. This gave him a great advantage, since the extensibility and transparency of the organ enabled him to examine its internal parts in their normal place and condition, undisturbed by the contact of artificial reagents. He applied this method to the observation of nerve-fibres, and the change which they undergo after division; and thus followed their gradual degeneration, from day to day, under the microscope.

One of his first and most important results was that the degeneration in the fibres of a divided nerve, below the point of section, extends through their whole length, reaching to its ultimate ramifications. After division of the glosso-pharyngeal nerve in the neck, he saw its degenerated fibres in the tongue, and even in the papillæ of the mucous membrane. He also established the fact that in a nerve once divided, the degeneration of the affected nerve-fibres is final; and that when the nervous functions are restored, it is by a true process of regeneration, that is, the growth of new fibres throughout the separated portion of the nerve.

But the principal merit in Waller's discovery was something additional. He did not rest content with its value as an acquisition, he made it serve as an instrument. He saw in the degeneration of divided nerve-fibres a means of investigation, which he at once put to further use. A nerve is often made up from fibres of different sources. It receives branches of communication from other nerves, and in the inosculating filaments between two different trunks, there may be fibres going or coming in either direction. In the nervous trunks and branches, these fibres are for the most part hopelessly intermingled, and it is impossible to follow them for any distance by ordinary dissection. But by dividing, in the living animal, a nervous trunk or branch near its source, Waller could afterwards trace its degenerated fibres, however erratic their course, or whatever their distribution. He communicated his results to the French Academy of Sciences,[1] under the title: *A New Method for the Study of the Nervous System; adapted for Investigating the Anatomical Distribution of the Nerves.*

The first application of the new method was in the frog's tongue. This organ is supplied by two nerves,

[1] Archiv für Anatomie, Physiologie, und Wissenschaftliche Medicin. Berlin, 1839, p. 405.

[2] Ibid., 1840, p. 270.

[1] Comptes Rendus de l'Académie des Sciences. Paris, 1851. Tome xxxiii., p. 606.

corresponding respectively to the glosso-pharyngeal and the hypoglossal. After dividing one of these nerves in the neck, and allowing time for its subsequent degeneration, Waller could determine the course and destination of all its fibres. He followed them throughout the frequent anastomoses of the two nerves, when the altered fibres could always be distinguished from the normal ones around them, and the two kinds were so different in appearance, that, as he expressed it, "there could be no doubt whatever as to the origin of either."

These results were obtained by repeated and accurate experimental investigation, and they have been fully corroborated by subsequent observers down to Vulpian,[1] in 1866, and Ranvier,[2] in 1878. According to Vulpian, six weeks after the division of the sciatic nerve, in a dog, no unaltered nerve-fibres could be found in the muscles of the corresponding foot; and in similar experiments by Ranvier on the rabbit, the terminal ramifications of the nerve in the muscles of the leg contained only nerve-fibres with disorganized and granular myeline.

The advantages in Waller's mode of procedure were so obvious and so readily verified, that it was soon generally adopted, and received the name of the "Wallerian method." It at once yielded, in the hands of its author, much interesting information. After division of the pneumogastric nerve on one side, in cats, at the level of the larynx, granular degeneration was found throughout its peripheral fibres, except in those joining it below, from the inferior cervical ganglion; all of which remained normal. Above this junction the nerve was wholly disorganized; below, it contained a mixture of fibres, normal and degenerated. It was thus made evident that the inosculating branches between the two nerves are given by the sympathetic to the pneumogastric, and not from the pneumogastric to the sympathetic.

Physiologists had often been at variance as to the origin and character of the *chorda tympani;* that remarkable filament of communication between the facial and lingual nerves. Was it a branch of the facial nerve, going to the lingual? Or was it an offshoot from the lingual, returning to join the facial? This point was determined by the method of section. Waller introduced his stylet into the middle ear, and divided the filament where it crosses the membrana tympani. Fifteen or twenty days afterwards, nearly all its fibres were degenerated between the point of section and the lingual nerve; that is, in the direction of their peripheral distribution. The chorda tympani was consequently shown to be a branch of communication *from* the facial nerve *to* the lingual.

In this way, many doubtful questions of nervous distribution received their solution. The granular degeneration of the divided nerve-fibres became an artificial aid to the anatomist, of the same value as the injection of minute bloodvessels with an opaque pigment. Even a single disorganized fibre could be distinguished among a crowd of normal ones; and in a mixture of the two, the numerical proportion of each could be fairly determined.

But Waller did not remain satisfied with this success. He determined to apply the same method which he had used for the nervous trunks and branches to the study of the nerve roots;[3] and in doing so, he opened a new chapter of nervous physiology, and greatly enlarged the field of his operations.

The history of these experiments is so well known that they only need to be stated in a few words. Waller had already shown that if a spinal nerve were divided at its exit from the vertebral canal, all its peripheral parts suffer degeneration. Motor and sensitive fibres are alike involved, and can be traced, in their disorganized condition, to their ultimate termination in both the muscles and the integument. On continuing the same mode of investigation within the vertebral canal, if the anterior root only were divided, the motor fibres alone degenerated in the trunk and branches of the nerve, while its sensitive fibres remained normal; if the posterior root were divided outside its ganglion, the sensitive fibres of the nerve degenerated, and the motor fibres were unaffected; and in both cases the portion of the nerve root still connected with the spinal cord preserved its normal structure. But if the posterior root were divided above the situation of its ganglion, two remarkable consequences followed. First, there was no degeneration of the nerve whatever outside the ganglion; and, secondly, that portion of the nerve root separated from the ganglion, but still united with the spinal cord, suffered complete degeneration.

These effects were repeatedly observed, under varied conditions, until there was no doubt in regard to them. In the frog, when both roots of a sciatic nerve were divided above the level of the ganglion, there was, of course, equal loss of motion and of sensibility in the paralyzed limb; but while all its muscular nerve-fibres degenerated, its sensitive fibres, distributed to the skin, exhibited no alteration whatever, even at the end of two months. Similar experiments on warm-blooded animals turned out in the same way. In dogs and cats, Waller utilized for this purpose the exceptional position of the second cervical nerve, the two roots of which remain distinct in these animals, until after emerging from the intervertebral foramina. He could thus operate on the nerve roots without opening the vertebral canal, and by this means he verified Magendie's discovery, that section of the anterior root destroys the power of motion; and that of the posterior root, the power of sensibility. But he demonstrated furthermore, that when both roots are severed above the level of the ganglion, all the motor fibres of the nerve degenerate, and all its sensitive fibres remain sound.

It is, therefore, evident that the immediate loss of action in a divided nerve, and its structural degeneration, are two independent phenomena, having nothing to do with each other. A motor nerve, when cut, ceases to excite voluntary motion, not because its fibres are incapacitated by degeneration, but because their physical continuity is broken at one point; and a sensitive nerve, under like conditions, can no longer communicate with the sensorium for the same reason. The proof of this is that, if we galvanize the motor nerve below the point of section, it at once calls out the action of its muscles; and a similar stimulus, applied to the sensitive nerve above its point of section, will be transmitted to the brain and produce the effect of a sensation.

But after some days a different condition shows itself in the peripheral part of the divided nerve. Its fibres are then unable to react under artificial stimulus, and their galvanization no longer produces muscular contraction. This is owing to their progressive degeneration, which requires time for its development, but which at a certain stage destroys the functional activity of the nerve-fibres. Simple paralysis of motion and sensation is consequently the *immediate* result of division of a spinal nerve. Its degeneration, with loss of irritability, is a subsequent and *secondary* result. The independence of the two is especially manifest in Waller's ex-

[1] Leçons sur la Physiologie du Système Nerveux. Paris, 1866, p. 243.

[2] Leçons sur l' Histologie du Système Nerveux. Paris, 1878. Tome ii., p. 349.

[3] His second communication to the French Academy, in 1852, was entitled "Experimental Researches on the Structure and Functions of the Ganglia." Comptes Rendus de l'Académie des Sciences. Paris, 1852. Tome xxxiv., p. 524.

periments on the spinal nerve roots; for, when both are divided above the level of the ganglion, the motor fibres of the anterior root become degenerated throughout their distribution in the paralyzed parts; but the sensitive fibres, from the posterior roots, remain everywhere sound in the integument of the same region.

From these facts Waller concluded that the two sets of nerve-fibres had different centres of nutrition; that the motor fibres of the anterior root were dependent for their structural integrity on connection with the spinal cord; while the sensitive fibres of the posterior root depended on their connection with the spinal ganglia. He was fully justified in claiming that his results were unequivocal, and "calculated to throw a new light on the relations of the nervous system."

For Waller's communications on this subject to the French Academy, he was awarded in 1856 the Montyon Prize of Experimental Physiology, by a committee consisting of Flourens, Rayer, Serres, Milne-Edwards, and Bernard. In reporting the decision of the committee, the Chairman, Bernard, begins with the following words: "The discoveries usually presented to us are of two different kinds. In some the facts have been already to a certain extent anticipated, and are mainly serviceable in their new form by increasing the precision of our knowledge, and by elucidating subjects previously obscure. The others, on the contrary, are unexpected. The principal feature in them is their novelty; and they enlarge the boundaries of science, not merely by the solution of particular questions, but still more by the new ideas and suggestions which they originate. It is to the last of these two categories that the present essay belongs."

It soon appeared that the committee were not mistaken in their estimate. The immediate result of Waller's researches was the discovery of the so-called "centres of nutrition" for nerve-fibres of different kinds. The existence of these centres of nutrition was fully demonstrated; although it was not quite plain, and has not even yet become so, in what way their influence is exerted. But there was also the additional discovery that the degeneration of divided nerve-fibres may take place in two opposite directions. It may be *centrifugal*, that is, from the point of section to the periphery; or, it may be *centripetal*, that is, from the point of section towards the spinal cord and brain. This fact afterwards became the most prolific source of further investigation.

Up to this point, Waller's experiments had been confined to the spinal nerves and nerve roots. In his last communication to the French Academy,[1] he goes a step further and traces the course of similar degenerations in the cord itself. He divided the spinal cord, in a dog, between the third and fourth lumbar vertebræ. After twenty days the cord was found to be reunited at the line of section. But above the section the posterior columns were disorganized for the space of about two vertebræ; while in the inferior segment the same columns, as well as the posterior nerve roots, were normal throughout. The anterior nerve roots, on the contrary, were completely degenerated for the first three pairs below the section; the alteration diminishing gradually in amount for the fourth, fifth, and sixth pairs. Thus, there may be, within the columns of the cord, as well as in its nerve roots, centripetal or centrifugal degenerations affecting exclusively particular nervous tracts.

This discovery corresponded with certain pathological observations in man made about the same time by Türck, and communicated by him to the Academy of Sciences at Vienna.[2] They were cases in which post-mortem examination revealed an old, morbid deposit in the brain, together with a structural alteration of the spinal cord on the opposite side. This alteration consisted mainly in an abundance of abnormal, granular cells, occupying the tissues of the cord and resembling those met with about the morbid deposit in the brain. The principal feature of the alterations in question was that they occupied definite longitudinal tracts, the rest of the cord being normal. By examining successive sections, at different levels, it became evident that from the lesion in the brain to the lower end of the spinal cord only certain bundles corresponded in situation with those which could be demonstrated by dissection in normal specimens of the cord, after hardening in alcohol.

Observing this correspondence, in certain cases, between the degenerated tracts and parts already known, the author was led to apply the same means of observation to the study of anatomical relations not so well understood. The attempt proved successful. The first fact which it brought out, was a distinction between the anterior and posterior segments of the lateral column. No such distinction can be shown by ordinary dissection, most of the nerve-fibres in both segments running in a direction parallel with each other, and between origins and terminations too distant to be traced. But in some of the cases mentioned, the morbid alteration of the lateral column was found only in its posterior part, the anterior part remaining sound; and this difference was so constant, in sections made at various levels, as to leave no doubt that there must be some anatomical distinction between the two segments of the column, extending through the greater part of its length.

It was also seen, in these cases, that, on approaching the upper end of the cord, the degenerated tract shifted its position forward and inward, and, at the medulla oblongata, crossed into the anterior pyramid of the opposite side. Thence it extended upward through the pons varolii, where the distinction was extremely evident, the transverse bundles of the pons being free from alteration, while its longitudinal bundles were deeply affected. It appeared, therefore, that the degenerated tracts had been invaded by a special alteration, confined to their own limits, and extending continuously, from the seat of the brain lesion, through the crus cerebri, the pons, and the anterior pyramid of the same side, and thence through the posterior part of the lateral column on the opposite side, quite to the lower end of the spinal cord.

This showed that there was a longitudinal tract of nerve-fibres, reaching for long distances in the cerebro-spinal axis, and having, so to speak, its own special centre of nutrition; and that when this centre of nutrition was disturbed or disorganized by local lesion, the subsequent degeneration might extend throughout the tract in question, while others in its immediate contiguity remained sound. The cases observed by Türck were accompanied by more or less hemiplegia; and while the brain lesion, as well as the degeneration of the pons and anterior pyramid, were, as usual, on the opposite side, that in the spinal cord was on the same side with the paralysis. Everything showed the degenerated portions in the spinal cord to be continuous with the opposite anterior pyramids and their extension in the crura cerebri, and consequently to represent the motor tracts of the cerebro-spinal axis. But while Türck followed the crossing of these tracts at the decussation of the pyramids, he also showed that in certain cases their crossing was incomplete; that is, although the bulk of a degenerated anterior pyramid crosses at the level of the decussation, and reappears below in the lateral column of the opposite side, a remnant of its fibres continue their downward course for some distance, on the same side. These direct col-

[1] Comptes Rendus de l' Académie des Sciences. Paris, 1852. Tome xxxv., p. 301.

[2] Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften. Wien, 1851, p. 288.

umns, visible more or less constantly in the cervical portion of the cord, are still known by the name of the "Columns of Türck."

But his most important results were those indicating the difference, in anatomical connection, between the anterior and the posterior parts of the lateral column. These two parts were distinguishable from each other by the granular deposit with which one was infiltrated while the other remained normal; and the deposit reappeared with such constancy at the same spot in successive sections, and crossed so distinctly at the decussation of the pyramids, as to show that it followed the course of an associated bundle of nerve-fibres. As this bundle represented, in the cord, the continuation of the crus cerebri and anterior pyramid above, the whole tract, from end to end, afterwards received the name of the "pyramidal tract." The first indication of the exact locality of this tract, in the lateral columns, was derived from the sections of Türck.

The same author made an incidental observation, afterwards seen to be very important, in regard to degenerations from local lesion of the cord itself. They were instances of paraplegia from compression or disorganization of the spinal cord at one point. In these cases the portion of the cord above the lesion, while nearly free from granular degeneration, nevertheless contained single degenerated tracts, always identical in situation, extending upward to the medulla and pons. But these tracts were not those found degenerated after a brain lesion, and the latter were entirely sound in the above-mentioned cases of injury to the cord. If one portion of the spinal cord, therefore, can degenerate in consequence of a lesion situated above it, another and an entirely different portion may be affected by degenerations coming from below.

So far, the knowledge of degeneration within the spinal cord had been mainly acquired from pathological observations in man. But about ten years ago Goltz, in Strasburg, undertook a series of investigations on the functions of the lumbar portion of the spinal cord, especially with regard to its influence on the sexual and urinary organs. His experiments were performed on young dogs by dividing the cord transversely at the lower end of the dorsal region, and then preserving the animals long enough to study the permanent effects of the operation. By adopting various improvements in the selection of animals, the operative procedure, and the subsequent treatment, he became very successful. The cord was divided without serious injury to the vertebral column or the external parts. Dogs of the proper age and organization were not dangerously affected by the operation, sometimes taking food within the first twenty-four hours, and generally regaining their natural appetite in a few days. The wounds healed in two or three weeks, and some of the animals were preserved several months, remaining paraplegic, but otherwise in good condition.

This was a valuable material for the study of degenerations in the spinal cord; and it was utilized for that purpose by Schieferdecker,[1] the assistant of Goltz, who was already familiar with the history and condition of the animals employed.

On examining microscopic sections of the cord in these cases, the granular degeneration of the pyramidal tracts was recognized. It was present in every instance, and had invariably taken a descending course, from the point of section to the lower extremity of the cord. This portion of the spinal cord, therefore, became altered after section, in the same way as a divided spinal nerve, that is, from the centre towards the periphery; and the degeneration of the pyramidal tract, whether it be due to a cerebral lesion, or to compression or transverse section of the cord itself, follows the same direction.

On the other hand, when a similar degeneration is met with in the posterior columns of the cord, it is always ascending. We have now the experience of Charcot,[1] to corroborate the earlier assertion of Türck, that such posterior degenerations invariably extend from the point of injury or disease upward towards the brain, and never in a downward direction. By this means the ascending and descending degenerations of the spinal cord were established with the same certainty as the centripetal and centrifugal degenerations of the nerve roots; and like them, were shown to occupy separate tracts, easily distinguishable from each other.

These facts greatly increased the confidence of physiologists in the value of degenerations as indicating the continuity and destination of nerve-fibres. It was evident from the first that a divided nerve-fibre degenerates because of its severance from some special nerve centre; and, once cut off from this centre, it becomes affected throughout its remaining length. When we see, in the spinal nerves, complete degenerations strictly limited to the ramifications of a single trunk, and similar alterations in the spinal cord equally confined to particular tracts, we can hardly refuse the conviction that these tracts also consist of continuous nerve-fibres following a common direction. Waller's experiments on the nerve roots show that when such a group of fibres meets a ganglion or centre of gray substance interposed in their course, then degeneration does not pass this point. Either the injured fibres receive a further accession of nutritive energy from the ganglion, or else they terminate in it ssubstance, and are then replaced by new fibres originating from its gray matter. This gives a special significance to the fact observed by Charcot[2] in regard to disease of the pyramidal tracts. These facts are manifestly the channels for voluntary motion in the spinal cord. The paralysis caused by either their morbid alteration or their experimental division shows that they are really the paths followed by voluntary motor impulses from the brain to the anterior nerve roots. But descending degenerations of the pyramidal tract, however complete in the spinal cord, do not usually extend to the motor nerves or nerve roots. This is easily explained on the assumption that the fibres of the pyramidal tract terminate in the gray substance of the anterior horn, while those of the anterior root have an origin of their own at the sam point. The nerve root, therefore, degenerates only when divided beyond its emergence from the anterior horn.

A further study of the posterior columns led to the additional discovery of two different kinds of degeneration, as well as to a distinction between different parts of these columns. Hitherto, the morbid alteration of nervous tracts had appeared only as e consequence of a local lesion, in either the ne es, spinal cord, or brain, extending upward or dowr ard from its origin, as if propagated in certain directi ns along the natural route of the nerve-fibres. These alterations of structure were, therefore, known as "secondary degenerations," because resulting from some primary affection in a different locality. But it appeared that certain tracts in the spinal cord might also be the seat of primary degenerations, originating within their own substance independently of lesions elsewhere. As these alterations often followed a similar course to those of secondary origin, occupying only their own tracts or system of fibres, they received the name of "systematic degenerations."

[1] Archiv für Pathologische Anatomie und Physiologie. Berlin, 1876, Band lxvii., p. 542.

[1] Leçons sur les Localisations dans les Maladies du Cerveau et de la Moelle épiniere. Paris, 1880, p. 247.

[2] Leçons sur les Maladies du Système Nerveux. Paris, 1877. Tome ii., p. 219.

The posterior columns of the cord were liable to both secondary and systematic degenerations. But these two affections occupied different regions, thus showing an anatomical distinction in the posterior column, like that already established between the front and back parts of the anterior column.

In the posterior column of the cord the inner part, next the median line, is a narrow band, visibly marked off from the remainder, in the cervical region, by a slight furrow on the surface. This is the *funiculus gracilis*, or the "column of Goll." At the medulla oblongata it diverges from the median line in an oblique upward direction, forming on the inner border of the restiform bodies the so-called "posterior pyramids." The columns of Goll are the seat of the ascending degenerations noticed by Türck. When they are affected in this way, their alteration extends unbroken from its starting-point, often quite to the level of the medulla oblongata; whence it is inferred that they are composed throughout of continuous fibres.

But the remainder of the posterior column is affected by degenerations which have a different form and different results. This portion is included between the column of Goll and the posterior nerve roots, and forms the outer part of the posterior column. It has not received a distinct name, but is important, owing to its connection with locomotor ataxia. It is regarded as made up of comparatively short fibres, originating and terminating in succession along the cord; for the reason that its secondary degenerations are never propagated to any considerable distance,[1] extending at most only two or three centimetres above their origin. But it is liable to systematic alterations of structure, mainly sclerosis, invading a large portion of its extent; and when such alterations occur, they are accompanied by symptoms of locomotor ataxia, never produced by structural disease in other parts. According to the observations of Charcot,[2] the columns of Goll may be completely degenerated without causing any signs of ataxia, while sclerosis of the outer part of the posterior columns is always accompanied by ataxic symptoms; and these symptoms are in proportion to the extent of the degeneration.

Lastly, the anatomical study of nervous tracts by the aid of secondary degenerations, has been carried into the brain itself. There is already a reasonable certainty of the extension of the pyramidal tracts through the anterior pyramids, the pons varolii, and the crura cerebri; and the fibres of the crus cerebri are manifestly succeeded by the diverging expansion of the internal capsule and the corona radiata. These expansions are, beyond question, for the most part, means of communication between the cerebral convolutions and the ganglia at the base of the brain; while the fibres of the crus cerebri connect the ganglia with the spinal cord below. But besides these interrupted communications, are there also direct fibres, running continuously from the motor centres in the cerebral cortex, through the corona radiata and internal capsule, into the pyramidal tract? The centres of motion about the fissure of Rolando might produce their effect when galvanized, either through the intervention of the cerebral ganglia, or more directly by means of continuous fibres. Such tracts of direct fibres have been sometimes imperfectly recognized in the examination of hardened specimens; but they have never been clearly demonstrated by this method, owing to the complicated interlacement of fibres in the upper part of the internal capsule. Their existence is mainly inferred from the course of descending degenerations in this region. According to Charcot,[1] destructive lesions of the cortex, in the anterior and posterior central convolutions, give rise to degenerations in the white substance which pass downwards through the internal capsule, crura cerebri, anterior pyramids, and lateral columns of the cord. These degenerations may be found without accompanying lesion of the cerebral ganglia; and they are not produced by morbid alterations in other parts of the brain than those about the fissure of Rolando. Similar observations, made during a period of fifteen years, point with much significance to a continuity of fibrous structure throughout this tract. If we remember the uniform progress of discovery already derived from these investigations, first in the nerves, then in the nerve roots, then in the columns of the spinal cord and the medulla oblongata, it is not presumptuous to expect from their future prosecution a corresponding success in the more difficult exploration of the brain.

The study of nervous degenerations has already borne fruit of great value. Like other researches of a similar kind, it was at first a matter of purely scientific interest, without any apparent bearing on the treatment or even the pathology of disease. But it has grown in importance with every additional observation, and it is now acknowledged to be an indispensable aid in investigating the morbid affections of the nervous system. It has extended our anatomical knowledge far beyond its previous limits. It has demonstrated the existence of nervous connections which could hardly have been detected in any other way. It has shown the relation between various forms of paralysis and the altered structure of particular nervous tracts; and it seems likely to yield still further results before its capacity is exhausted. It began with the cicatricial tissue between the ends of a divided nerve, and it has now reached the intricate region of the white substance of the cerebral hemispheres.

ON THE PHYSICAL DIAGNOSIS, BY MEANS OF PERCUSSION AND EXPLORATION BY PUNCTURE, OF PERITONITIS

WITH AND WITHOUT PERFORATION OF THE ALIMENTARY CANAL, AND THE EMPLOYMENT OF ASPIRATION IN CASES OF PERFORATING PERITONITIS.[2]

BY AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

OF the various causes of acute diffuse peritonitis, traumatic and puerperal cases being excluded, the most frequent is perforation of the alimentary canal. It is highly important to recognize this condition at the bedside, in individual cases, for several reasons. One reason relates to the prognosis. The prognosis is extremely unfavorable if there be intestinal or gastric perforation. Another reason has reference to the use of opium in the treatment. In all cases of acute peritonitis, opium is the "sheet-anchor" in the treatment; but there is added a special object in the use of opium if perforation exist. Recovery is possible only by such a degree of induced arrest of peristaltic movements as will allow adhesion to take place at the point of perforation. The practice of

[1] Leçons sur les Localisations dans les Maladies du Cerveau, pp. 156, 166.

[2] Read before the Medical Society of the State of New York, February 8, 1882.

the future may furnish another reason. It may be that laparotomy will be found to be a life-saving operation in some cases. Opening the abdominal cavity, closing the perforation by proper surgical means, and washing out all irritating matters, it is not highly improbable will be a method of treatment sanctioned by its successful employment.

Correlatively it is of importance to be able to exclude perforation, at the bedside, in cases of acute peritonitis. One object of this paper is to invite attention to the proof against perforation afforded by a physical sign, namely, hepatic flatness on percussion. The exclusion of this cause is a ground for a favorable prognosis; it is to be considered in the use of opium in the treatment, and, at a future time, perhaps in deciding upon laparotomy.

Under normal conditions, flatness on percussion extends from about the sixth rib on the mammary line to the site of the lower border of the liver, that is to the level of the false ribs. In cases of perforation of the stomach or of the intestine, gas in greater or less quantity escapes into the peritoneal cavity. The exceptions, if there be any, must be extremely rare. Gas within the peritoneal cavity, the patient recumbent on the back, will separate the anterior surface of the liver from the thoracic wall. This is probably true without exception, provided there be not adhesion of the entire anterior surface of the liver as a result of peritonitis, and adhesion sufficient to prevent the entrance of gas between the liver and the chest-wall is rare. The presence of gas between the anterior surface of the liver and the chest-wall gives rise to tympanitic resonance on percussion. I assume that in cases of peritonitis with perforation, the normal hepatic flatness is always supplanted by tympanitic resonance. This statement is shown by experiments on the cadaver and by clinical observations.

The points which I make are these: If perforation be the cause of the peritonitis, there is more or less gas in the peritoneal cavity; a stratum of gas will then separate the liver and the chest-wall, giving rise to tympanitic resonance on percussion, and, hence, if there be persistence of the normal hepatic flatness, perforation as the cause of the peritonitis may be excluded.

It is only within a short time that my attention has been specially directed to this proof against intestinal or gastric perforation in cases of peritonitis. During this time, however, the following cases under my observation have exemplified its practical application.

In the case of a middle-aged man, seen with Prof. Erskine Mason, of New York, and Dr. Furman, of Tarrytown, the history and symptoms pointed to perforation of the appendix vermiformis of the cæcum. The pain originated in the right iliac fossa; resistance to pressure was felt in this situation, and the abdomen was notably tympanitic. Moreover, the general symptoms denoted so much gravity that a fatal termination was considered as highly probable. Hepatic flatness on percussion, however, was always found, and the recovery of the patient may be considered as rendering it almost, if not quite, certain that there was not intestinal perforation.

A woman of middle age, seen by me in consultation with Dr. Lewis and Dr. Hutchison, of Brooklyn, presented the symptoms of acute diffuse peritonitis, with enormous tympanitic distention of the abdomen. Hepatic flatness was well marked, and on this fact perforation of the alimentary canal was excluded. Death took place within twelve hours after my visit. The autopsy showed the recent passage of gall-stones through an ulcerated opening into the duodenum. Two gall-stones were found in the small intestine. There was no gas in the peritoneal cavity.

In the case of a young women, a patient of Dr. Burrall, of New York, acute diffuse peritonitis was developed in the course of typhoid fever. There was moderate tympanites in this case. Hepatic flatness was found on percussion. The case ended fatally, and there was no autopsy. That intestinal perforation had not taken place, was a fair inference, irrespective of the hepatic flatness, from the absence of the gravity of symptoms which perforation occasions, and from the fact that death did not place for at least a week after the occurrence of the peritonitis.

So far as these few cases go, they show that hepatic flatness on percussion is proof against perforation of the alimentary canal as the cause of an existing acute peritonitis.

A larger collection of cases is desirable, and a motive in submitting a paper at the present time is to interest others in testing the value of this physical proof.

Assuming that hepatic flatness on percussion is proof against perforation of the alimentary canal in cases of peritonitis, it cannot be assumed that tympanitic resonance over the hepatic region is always proof of perforation. The possibility of the colon being pressed upwards, so as to lie between the anterior surface of the liver and the chest-wall, has been demonstrated. But this occurrence is not necessary in order to explain hepatic tympanitic resonance on percussion. It happens not very infrequently that when the transverse colon is much distended with gas, tympanitic resonance is conducted upwards, so as to meet the pulmonary resonance. This conduction upwards of tympanitic resonance from the colon renders the evidence afforded by percussion of the site of the lower margin of the liver very unreliable. If reliance were placed upon percussion, it would be necessary sometimes to conclude that the liver is wanting in its normal situation. This conclusion was actually reached in a hospital case under my observation. The patient had cirrhosis of the liver, with some hydro-peritoneum, and a greatly enlarged spleen. It was reported to me as a case of transposed abdominal viscera, the liver being situated on the left side; and the tympanitic resonance in this case extended upwards to the upper margin of the liver, where it became merged into the pulmonary resonance.

It is not an uncommon error to infer diminution of the size of the liver by measuring, on the mammary line, the distance between pulmonary and tympanitic resonance. On the other hand, per-

cussion is not to be relied upon for determining enlargement of the liver, for the reason that the upper boundary of tympanitic resonance is no criterion for locating the lower margin of the organ. Here, however, we have a resource against the unreliability of percussion, namely, palpation. The sense of resistance to finger-pressure may be relied upon in ascertaining how far the liver extends below the false ribs, and the pulmonary resonance on percussion is reliable as indicating its upper boundary.

In order to show that the presence of air in the peritoneal cavity causes hepatic flatness to disappear, and gives rise to tympanitic resonance over the liver, the following experiment on the cadaver was made by Dr. Stone, House Physician of the Third Medical Division, Bellevue Hospital, at my request, and in my presence. It is proper to state that the experiment was suggested by Dr. Corwin, senior assistant of the division.

The body of a man, six hours after death, presented considerable tympanitic distention of the abdomen. Hepatic flatness was limited on the mammary line to a space about an inch in its vertical diameter. Air was injected into the peritoneal cavity through a small-sized cannula, which was attached to Bowditch's aspirating instrument. The trocar was introduced near the umbilicus. The hepatic flatness quickly disappeared, giving place to tympanitic resonance.

The body of a woman, fourteen hours after death, presented complete collapse of the abdominal walls, and flatness on percussion below the sixth rib. There was considerable rigidity of the abdomen. Air was readily injected into the peritoneal cavity, causing distention and tympanitic resonance over the whole abdomen. The hepatic flatness at once gave place to tympanitic resonance.

In each of these experiments it was difficult to remove the air through the small cannula by pressure over the abdomen sufficiently to restore the hepatic flatness on percussion.

In order to obtain positive proof of the presence of gas within the peritoneal cavity, whenever, in cases of peritonitis, tympanitic resonance extends over the region of the liver, there can be no objection to an exploratory puncture with a small trocar and cannula. The puncture should be made within the hepatic region, lest, possibly, if made elsewhere, the intestine might be wounded. The escape of gas through the cannula is easily perceived by *the touch* and by the odor. Air injected, and allowed at once to escape, acquires an intestinal odor. If desirable, the gas could easily be collected by attaching to the cannula an oiled-silk bag; or it might be aspirated and collected in a glass receiver.

The exploratory puncture thus supplies what is lacking as regards proof of perforation afforded by percussion, and by means of percussion and the exploring trocar, in cases of peritonitis, it may be positively determined whether or not perforation exists. If hepatic flatness on percussion remain, there is no perforation of stomach or intestine. If, on the other hand, tympanitic resonance be found to extend over the region of the liver, all doubt as to the existence of a perforation is removed by an exploratory puncture in that region. It is hardly necessary to add that care is to be taken, in introducing the trocar, not to penetrate the liver; not that the wound will do harm, but because the peritoneal gas will not then escape through the cannula. The liver has not been penetrated if, after withdrawing the stylet, the end of the cannula which has been introduced be freely movable.

A late writer in a standard work on practical medicine (*Ziemssen's Cyclopædia*), says of acute inflammation of the peritoneum, "the only difficult question is whether the peritonitis be with or without perforation. To decide this point, we ought not to rely on any one single well-established physical sign, but make an accurate digest of the entire group of phenomena. Notwithstanding, the diagnosis in some cases must remain undecided." (Vol. viii., p. 208.)

By means of the simple methods submitted in this paper, as it seems to me, the question, whether the peritonitis be with or without perforation, is divested of all difficulty, and may always be decided positively.

It is assumed, in this paper, that the presence of gas within the peritoneal cavity in cases of peritonitis, always denotes perforation of either the stomach or intestine. The question may be asked, is not gas sometimes a result of chemical changes in morbid products within the peritoneal cavity, perforation not existing? Without denying the possibility of gas being thus derived, it is, as I believe, a warrantable statement that the instances, if there be any, are so rare that they may practically be disregarded.

Recovery from perforating peritonitis requires, first, agglutination by means of fibrous exudation, and, next, permanent adhesion, by means of proliferating tissue, to some part with which the intestine or the stomach is in contact at the site of the perforation. It is obvious that the presence of gas within the peritoneal cavity must interfere with this requirement for recovery. Hence arises the inquiry whether the removal of this gas may not prove to be an important measure in the treatment.

Aspiration is probably the safest and best method for the removal of the gas. When air is injected into the peritoneal cavity through a small cannula, its entire removal is not easily effected even by firm pressure over the abdomen. The entire removal is shown by the disappearance of tympanitic resonance over the liver, and this resonance was found to remain after firm pressure, in the experiments on the cadaver which I have related. Moreover, pressure on the abdomen sufficient to remove the gas in cases of peritonitis, would perhaps do more harm than the presence of the gas. Of the different aspirators, I should prefer either my adaptation of Davidson's syringe to thoracentesis, or Bowditch's instrument, for the reason that they are more readily under control, as regards the suction-force, than the aspirator of Dieulafoy. The puncture made by a small trocar causes so little pain that it might be repeated whenever the gas accumulated within the peritoneal cavity; or the cannula, closed by a stop-cock, might be allowed to remain, and aspiration repeated as

often as the resonance over the liver denoted the presence of gas. The aspiration might include the withdrawal not alone of gas but of effused liquid. The removal of the latter is desirable, inasmuch as it may separate the site of the perforation from an adjacent part, and thus prevent closure of the perforation.

In order to demonstrate the possibility of the removal of gas from within the peritoneal cavity by aspiration, the following experiment on the cadaver was made, at my request, by Dr. Thatcher, junior assistant, Bellevue Hospital: A trocar was introduced in the region of the iliac fossa and attached to Bowditch's aspirator. The injection into the peritoneal cavity of the air contained in the syringe twice, was sufficient to substitute tympanitic resonance for flatness in the hepatic region. Afterwards the trocar was introduced over the liver, and, by suction with the instrument, the tympanitic resonance was made to disappear and give place to the hepatic flatness which existed before the injection of air.

THE SIGNIFICANCE OF PAIN REFERRED TO THE EAR.[1]

BY D. B. ST. JOHN ROOSA, M.D., LL.D.,
SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, NEW YORK.

IT is notoriously difficult to estimate accurately a subjective symptom, but pain takes a high place in the important testimony given by the patient himself. It brings with it so many objective signs in the expressions of the face, and the gestures, and in the play of the emotions, that we all attach much importance to it as a diagnostic symptom. When we have made all due allowance for the nervous disposition which exaggerates the least pain until it is described as unbearable; when we have noted the delicacy or pusillanimity of temperament which tolerates no discomfort, we still find in pain an important indication of the true state of the organ supposed to be diseased. The symptom of pain in the ear is no exception to this rule. We may find in it, perhaps, much that is significant and suggestive. If the Society will grant me their indulgence for treating of a somewhat commonplace subject, I will venture to formulate the suggestions which are made by the discovery of the existence of pain in the ear. It is the symptom commonly known as earache.

1. *Foreign Bodies in the External Auditory Canal.*—The entrance into the external auditory canal of a living animal, such as an earwig, or the generation of a maggot in the same part may, and generally does, cause severe pain. The diagnosis of the cause in this instance is easy. Ocular inspection will determine it in a few seconds. The means of relief are simple. Syringing with warm water, or filling the canal with fluid, will readily remove the insect. As to the maggot, it will be necessary to kill the grub by the use of such an agent as Labarraque's solution, or by the vapor of chloroform, before it can be removed by syringing.

Inanimate foreign bodies, which are generally placed in the ear by children, or irresponsible adults, do not usually cause pain, unless they have been pushed down into the canal, so as to press upon its sensitive integument or upon that of the drumhead. Nor is there any danger unless this has occurred. This is a hint to us to avoid haste and severe means in removing such an offender.

Impacted wax, in a few cases, causes severe pain in the ear. The diagnosis here is also perfectly easy, and the means of relief ample. In the majority of cases, inspissated cerumen, while a foreign body, may cause tinnitus and impairment of hearing, it does not produce pain. In the cases which I have seen where pain occurred, there has been an inflammation of the integument of the canal, so that the wax has been glued, as it were, to it; or it has pressed upon the drumhead. This pressure upon the membrana tympani, from a plug of hardened material, may not occur until the wax has remained in the canal for months. I have long thought that the cause of impacted cerumen is to be found in an inflammation of the canal, and that the inflammation, if such there be, causes a swelling and adhesion of the epidermis, perhaps of the integument itself, to the cartilage or periosteum of the canal. It is in these cases where the inflammatory origin is decided, that I have seen pain particularly prominent as a symptom. As I have already indicated, this particular condition is a very rare one.

2. *Furuncles and Diffuse Inflammation of the External Auditory Canal.*—The pain from furuncles or from diffuse inflammation, is very often extremely severe. But it may usually be distinguished from that caused by inflammation of the middle ear, even without ocular inspection, although I am far from advising any one to thus venture a diagnosis.

Unfortunately, pain from an inflammation of the canal, is not so easy of immediate relief as is pain from the more deeply-seated and dangerous lesion. An inflammation of the canal may extend to the auricle and to the superficial tissues of the mastoid process. An inflammation of the connective tissue and perichondrium of the auricle, is extremely painful, and I know of no adequate means for its immediate relief. It is fortunate that it is rare.

But even when this occurs, the pain from an inflammation of the canal is not to be compared with that from a true periostitis of the mastoid process, or to that from an inflammation of the little tympanic cavity. In rare cases it is probable that the inflammation of the canal becomes periostitis by direct extension, and in such instances the pain will be very severe, but the means of relief are sufficient. An incision which divides the inflamed periosteum, will give it in a few moments. A periostitis of the canal cannot be distinguished by the character of the pain from a periostitis arising from an inflammation of the middle ear. The extension from this part is as dangerous as the extension from the tympanic cavity, and, as I have said, the pain from furuncles or diffuse inflammation of the canal is not so easily relieved as the same symptom arising in the course of the more serious inflammation of the tym-

[1] Read before the Medical Society of the State of New York, February 9, 1882.

panic cavity, Eustachian tube, and the mastoid cells.

The probable consequences of an inflammation of the canal, either diffuse or circumscribed, are not serious; and we may not be troubled as to the future of the patient's hearing, even though we are not able to promptly relieve the pain. The means upon which I rely for the *mitigation* of the pain from furuncular or diffuse inflammation of the canal are, 1, the warm douche, and the use of steam; 2, poultices applied behind and in front of the ear, and *in* the meatus; 3, incision of the inflamed tissues; 4, the administration of some preparation of opium.

Large poultices enveloping the auricle, as has been long since shown, are apt to set up chondritis, a tedious disease of the auricle, and they may also cause granulations to rise in the auditory canal. Some times the warm water acts like a charm to quiet all the pain from this form of inflammation. It should be used by means of a fountain syringe, or Fayette Taylor's douche, or any other siphon arrangement which may be at hand. The ordinary syringe will never be of any value in the application of the douches. The stream must be continued without interruption for a long time, in order to mitigate pain. When the warm douche fails, poultices, applied as I have stated, will sometimes accomplish very much; and when all these fail, a free incision through the swollen tissues down to the bone in the osseous canal, and well into the cartilage in the cartilaginous, will cut off the severity of the attack. But in many of the tedious cases all these agencies but mitigate the symptoms until the proper conditions of life replace the improper ones under which this disease originated, and tonics, change of air, and time have wrought a cure unmarked by relapses. It is an interesting clinical fact that leeches are usually of no avail whatever in furuncles of the auditory canal, and of very limited value in diffuse inflammation, important as their use is in subduing the pain of severe inflammations of the middle ear.

I have carefully studied all that is claimed for sulphide of calcium in subduing pain in this part of the ear, and I have occasionally administered it to prevent frequent relapses of furuncular inflammation, but as yet I see no reason to change my opinion that the exhibition of such drugs as a means of relief for pain caused by local swelling and tension in an inaccessible part, inaccessible as to the relief of tension, is simply a *renaissance* of the exploded tenets of one of the sects in medicine.

Pain in the ear from external inflammation is much more rare than from a morbid process in the middle ear. From the character of the pain alone it would be very difficult to make a diagnosis, and yet it may be said, in general terms, that pain from inflammation of the middle ear may be distinguished from that from boils or from that *rara avis*, otalgia, by its general characteristics of intensity. The pain from the serious disease of the middle ear is often agonizing and overwhelming, continuing without interruptions of composure, while that from furuncles and otalgia is comparatively bearable.

3. *Disease of the Middle Ear, that is to say, of the Tympanitic Cavity, Eustachian Tube, and Mastoid Process is a prolific cause of Pain.*—This pain, when intense, is a serious symptom. The well-being, often the life, of the patient, may be involved in its proper interpretation. If it be intense and arise from pressure in the tympanic cavity or the mastoid cells, from tension of the infiltrated periosteum, or from pressure by swelling of the Eustachian tube, no drugs, not even doses of opium, or its preparations, much less any of the recently recommended medicines, such as sulphide of calcium and pulsatilla, will be of any avail at all, until nature or mechanical means, such as leeches and the knife, and inflation of the stopped-up chambers have evacuated the pus or mucus, disgorged overfilled bloodvessels, or divided the tensely stretched membranes.

Slight pain is readily relieved by the warm douche and by poultices. Those who believe in the mysterious virtues of drugs in preventing maturation may add them to the mechanical means in these cases. But in the mild forms of middle-ear inflammation they are unnecessary, and in the severe ones wholly useless. Confinement of the patient to a warm room, promotion of the moisture of the skin, perfect tranquillity of the body, will be found necessary adjuvants in the treatment of pain from disease of the middle ear, while these things will accomplish very little, if anything, in relieving that from boils.

The means for determining the origin of pain in the ear are ample, and yet as we all know, perhaps, the conclusion is often hastily reached that the disease from which it arises is one of the canal and not of the middle ear. A serious disease is thus mistaken for one which is unimportant by comparison. It may be, in the opinion of your speaker, taken almost for granted that severe earache, in ninety out of every one hundred cases, is caused by inflammation of the middle ear. I would adopt means for its relief as follows: 1, the warm douche; 2, leeches. These will scarcely ever fail in cases seen within one or two hours of the beginning of the pain. Sometimes, however, nature anticipates any ordinary surgical assistance and relieves the case by the bursting of the enlarged bloodvessels through the membrana tympani within an hour of the beginning of the attack. [Otitis media hæmorrhagica.]

But even if the pain has existed for days, the proper action of leeches will cut it off, often before the leeches have dropped from the tragus of the mastoid, while the warm douche will complete the cure.

I have been speaking of severe pain, of pain which prevents sleep even though powerful anodynes are used, pain which causes the bravest man to groan with agony or writhe with restlessness in this unintermittent disease. The pain from periostitis of the mastoid is also relieved as readily as that of tension of the tympanic cavity, if seen early, by leeches, by poultices; and if seen late, by division of the tissues down to the bone.

There is much disease of the middle ear, active though it may be, which is not characterized by great pain, and in which the beneficent power of time and nature will accomplish a great deal. The wise observer will carefully discriminate between

severe cases and those which need mild treatment. But that form of disease characterized by the pain which I have endeavored to describe, will sometimes, nay, often, work destruction of the organ of hearing, and even cause the loss of life, if not relieved at once. When it occurs it cannot be trifled with, and, as yet, no means have displaced those known as local antiphlogistics.

4. *Otalgia.*—Pain in the ear of a severe type, and lasting but for a second at a time, sometimes occurs in the course of chronic non-suppurative disease of the middle ear. The symptom is not an important one. Such pains do not interfere with the usual health of the patients unless they are anæmic or hysterical. What may be called typical otalgia, that is, pains in the ear without apparent lesion, rarely occurs. When it does, it may depend upon carious teeth, or upon rheumatism or syphilis.

In closing this essay upon the significance of pain in the ear, I venture to state, whatever æsthetics may owe to Mr. Oscar Wilde, humanity remains under great obligation to his father, the great Irish Baronet, who, some thirty-five years ago, first plainly drew the line between the extremely rare affections of the ear, which may be denominated nervous, and those which are of an inflammatory character. He plainly indicated to us the importance of leeches, and of division of the periosteum for the relief of serious pain in the ear.

The debt which we owe him was increased by that due to Hermann Schwartze, of Halle, for having revived the operation of paracentesis of the membrana tympani in cases of over-distention of the tympanic cavity. These means remain, as yet, unsupplanted for the relief of the symptom which is generally caused by what may be called mechanical influences. He who discards them in the proper cases, does so at the peril of the integrity of the organ of hearing, perhaps even to the life of his patient; true though it be, that one may escape from even such peril after weeks of unnecessary suffering, with neither damage to his hearing nor loss of life.

MEDICAL PROGRESS.

HYDRATE OF CHLORAL IN ACUTE GASTRO-ENTERITIS IN CHILDREN.—Dr. ADOLPHE KYELLBERG (*Nordesk Med. Arkiv.*, Bd. IV.) concludes that the principal cause of difficulty in treating this affection is the great irritability of the stomach, and that hydrate of chloral serves better than any other drug to check the violent vomiting by which all medicines and foods are rejected, and besides soothing the child, will often help to arrest diarrhœa. He administers it in the form of an injection, preferably after the bowels have been moved, in doses of 25 to 30 cgrms. for children of from five to six months old, and from 50 to 60 cgrms. to children of twelve to fifteen months of age, only a dessert-spoonful of fluid being used. The enemata may be repeated two or three times daily, if required, the doses also being increased, if they appear to be too small, or it may be associated with other drugs, such as iced champagne or brandy for the vomiting, opium internally or as an enema for the diarrhœa, warm baths with mustard for albuminuria, if present, and stimulants for collapse. Finally, to increase the effect of the chloral, the author is accustomed to add 1 grm. of the *tr. thebaica* to the enema, and when stimulants are required, 5 to 15 drops of Hoffman's anodyne.—*Journ. de Méd. de Paris*, Dec. 24, 1881.

EXTRA-UTERINE PREGNANCY: EXPULSION OF THE FŒTUS BY THE RECTUM: CURE.—On the 19th of December, 1879, Dr. BULTEAU was called to a woman suffering from terrible abdominal pains and continuous vomiting; her face was contracted, pulse small, and abdomen distended and painful in the left iliac fossa. The patient was thirty-three years old, had generally been in good health, and had had a miscarriage six years previously, since when her menstrual periods had been irregular. A diagnosis of pelvic peritonitis was made, and the symptoms disappeared under treatment with opium, an irregular tumor, however, remaining in the left iliac fossa. The general health continued to fail, vomiting persisted, and it was thought at one time that there existed a cystic sarcoma of the uterine appendages. Several months later the patient had an abundant sanguinolent diarrhœa, after which the tumor diminished considerably in size, and one month later, a femur of a fœtus of eight months was passed by the anus, and at different intervals all the other bones of the fœtus escaped by the same means. Ten months after the commencement of these deliveries the patient had entirely regained her health.—*Union Méd. du Nord-Est*, Oct. 15, 1881.

THE TRUE VALUE OF NERVE-STRETCHING IN THE TREATMENT OF THE PRINCIPAL SYMPTOMS OF LOCOMOTOR ATAXY.—At the congress of German naturalists, held in Salzburg, last September, the question of the value of nerve-stretching in locomotor ataxy was thoroughly discussed, and all were agreed that, after a transient stage of amelioration, the disease advanced unchecked. This opinion has since been confirmed at the meeting of the Verein für innere Medicin of Berlin, held on the 31st of October, when Drs. Bernhardt, Leyden, Litten, Goldammer, and Israel cited numerous facts which placed the conclusion beyond doubt, that elongation of the great nerve-trunks in locomotor ataxy can lessen the darting pains for a few weeks, and renew cutaneous sensibility and equilibrium; but the pains, driven from their original seat, appear in the trunk, the loss of equilibrium is soon more marked than before, and the skin again loses its sensibility.—*Deutsche Med. Woch.*, Nov. 19, 1881.

AN IMPROVED VAGINAL TUBE.—J. HOCKS (*Centbl. f. Gynäkol.*, No. 19, 1881) draws attention to the occurrence of uterine colic with sickness, etc., from the use of the vaginal douche, which he attributes to the introduction of either air or fluid into the uterine cavity, in cases where, either from retroversion or gaping of the os, the end of the vaginal tube may have accidentally lain directly opposite the opening of the cervix. He recommends the use of a spindle-shaped tube, which at its farther end divides into two smaller tubes, these, however, becoming again continuous, thus inclosing an oval space about one and a half inches long. The injection escapes by means of perforations on the inner aspects of these smaller tubes, and the end of this instrument, if introduced into the cervix, will effectually plug it. In regard to the use of the douche during menstruation, the writer states that by using such a tube, and thus preventing the possibility of fluid entering the naturally gaping cervix, and by carefully assimilating the temperature of the water to that of the body, not only is there no danger, but better results are obtained than during the inter-menstrual period.—*Edin. Med. Journ.*, Jan., 1882.

TEMPERATURE OF ACUTE ABSCESS.—M. ASSAKY has recently undertaken some experiments under Prof. Gosselin's direction, to determine by direct measurement, the temperature at the seat of suppurative inflammatory action of acute abscesses in one hundred and twenty-three cases, and compare it with the local temperature of other parts of the body. M. Assaky found:

1. The temperature in the interior of an acute subcutaneous abscess, wherever located, or whatever the age or constitution of the patient, varies from 99.5° to 101.3° Fahr.

2. The cutaneous temperature over the seat of the abscess is always from 0.9° to 4.5° higher than that of a corresponding point on the opposite side of the body.

3. The localized elevation of temperature tends to disappear as the abscess approaches cure: the course of the temperature of the abscess is independent of that of the general body-temperature.—*Gaz. Méd. de Paris*, Dec. 3, 1881.

PARAMYOKLONUS MULTIPLEX.—Under this name Prof. FRIEDREICH describes (*Virchow's Archiv*, December, 1881,) a case of clonic contractions of a number of symmetrical muscles of the lower and upper extremities. The patient, a man aged fifty, the subject of cirrhosis of the right lung, presented the following symptoms. There were short, quick, rapidly-recurring contractions of the biceps, triceps, and supinator longus of the arms, and the vastus rectus femoris, adductors, biceps femoris, and semitendinosus of the thighs. No other muscles of the extremities or trunk were involved. The contractions were not fibrillar, but affected the entire muscle, causing it to swell and harden. They were not always forcible enough to move the limb, though sometimes the arm would be flexed by the biceps, or the hand supinated by the action of the supinator. The contractions were not rhythmical, but separated by irregular, brief intervals. Though symmetrical muscles were affected, each contracted independently. When in action, a sound could be heard with the stethoscope resembling the first sound of the heart. The frequency and intensity of the contraction varied in a quiet state, 10 to 20, in a most active, 40 to 50 per minute. Occasionally they would cease for one-quarter to one-half an hour. Sometimes the contractions would follow each other with great rapidity, and the muscle would pass into a state of tetanus, lasting for a few seconds and accompanied by pain. As a rule, they were strongest and most frequent when the patient was at rest in the evening, and would at times cause pain enough to prevent sleep. Not infrequently he was aroused from sleep by a painful cramp of the muscles of the legs, which would then be drawn up towards the abdomen. During sleep the movements stopped. When patient made voluntary movements or used the limbs actively, the contractions ceased, so that they did not interfere with his work. The power of the affected muscles was not impaired. Electrical excitability, to both currents, normal; mechanical excitability also natural. On the other hand, the reflex excitability was decidedly increased. Even exposure of the limb to the cool air intensified the contractions. Pinching the skin or other stimuli acted in the same way. No ankle clonus, but the patellar reflex was greatly exaggerated. All of these phenomena, the spontaneous contractions and the increased skin and patellar reflexes, were much more marked on the right side. Sensibility normal. No vaso-motor or secretory disturbances. No atrophy of affected muscles. No cerebral or papillary symptoms.

Patient attributed the trouble to a severe fright which he had received five years before; he became pale and had a sensation of rigidity of the entire body, which recurred in a quarter of an hour. Fourteen days after he first noticed the twitching, which gradually became more intense, and lasted up to the date of his admission, on 29th of April, 1880. Under galvanism the frequency and intensity of the movements rapidly abated, and in a few days entirely disappeared.

Prof. Friedreich believes that a local muscle or nerve affection could be excluded, and explains the symptoms on the view of increased excitability in certain groups of nerve cells in the anterior horns of gray matter of the cord; not of the nature of an inflammatory state, but rather a functional disturbance.

With regard to the etiology, it had no connection with the chronic lung trouble, but would appear to be directly related to the fright, so that it may be regarded as a remarkable and peculiar form of *fright neurosis*.

SALICYLATED STARCH IN ECZEMA.—KERSCH (*Wiener Med. Blatt.*, No. 1, 1881) strongly recommends salicylated starch in the treatment of eczema. It is prepared by gradually mixing small quantities of pure starch with a 2 to 3 per cent. alcoholic solution of salicylic acid. When the starch has settled, the quantity of the solution present should be sufficient to furnish a layer over it. The residual solution should then be poured off, the salicylated starch pressed in stout muslin, and dried at a temperature of 176° Fahr. The eczematous patches are first deprived of their scales by the use of a 2 per cent. solution of carbolic acid and potash soap, then dried with absorbent antiseptic cotton, subsequently moistened with a 2 per cent. alcoholic solution of salicylic acid, and then thickly covered with the salicylated starch. The remedy, even allowing for Kersch's enthusiasm, seems to have acted well, and is worthy of more extended trial.—*Dublin Journ. of Med. Science*, Nov., 1881.

VENOUS CONGESTION AND CIRRHOSIS OF THE LIVER IN DIABETES.—M. LECORCHÉ draws the following conclusions from an essay on this subject:

1. Congestion of the liver is usually, if not invariably, found in the course of diabetes; it is dependent upon the excessive functional activity of this organ, which itself is the cause of the disease.

2. Atrophic cirrhosis of the liver exists merely as a coincidence with diabetes, and can be only indirectly due, according to the author, to the congested state of the organ. He believes it to be due to the large amount of liquid consumed by diabetics.—*L'Union Méd.*, Dec. 29, 1881.

KOUSSO RESIN.—Prof. ARENA (*Prak. Arzt., No. 3*) states, in regard to the action of fresh and old kousso as a vermicide, that this substance loses its activity by keeping, and this is due to the alteration in the resin, which is the active principle. The fresh resin is green, with a somewhat bitter and unpleasant taste. The old resin is yellow, and without bitterness.—*Practitioner*, Jan., 1882.

FORCED ALIMENTATION IN PHTHISIS.—Dr. DESNOS points out a number of inconveniences or accidents which may follow the use of forced feeding as recommended by M. Debove, of which the following is a summary.

The method can produce intolerance of the stomach and painful cramps, which may be sufficiently severe to necessitate the abandonment of forced feeding. On the other hand, this intolerance may, in certain cases, be overcome by introducing the fluid very slowly and intermittently, and in smaller quantities than usually advised. It is advisable to select the periods when fever is absent for the administration of the food, and in cases where milk causes uncontrollable diarrhœa, another article of food must be selected.—*Bull. Gén. de Thérapeutique*, Jan. 15, 1882.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, FEBRUARY 11, 1882.

NATIONAL PUBLIC HEALTH LEGISLATION.

I. THE ADULTERATION OF FOOD AND DRUGS BILL.

AMONG the four thousand odd hundred bills which have been already introduced into the present Congress, there are several which are of special interest to physicians and sanitarians. At present we propose to remark upon but one of them, reserving others for future examination.

We say but one, although there are three bills relating to the adulteration of food and drugs noted in the Record, namely, H. R. 1039, introduced by Mr. Hardenbergh, of New Jersey; H. R. 1080, introduced by Mr. Flower, of New York; and S. 649, introduced by Senator Miller, of New York. A very slight examination, however, shows that these bills are identical in all respects, each being, in fact, a copy of the bill prepared and presented towards the close of the last Congress under the auspices of the National Board of Trade.

The essential features of this bill may be summed up as follows: It forbids the introduction of adulterated food or drugs into the United States or their transport from one State to another. It forbids the manufacture or sale of adulterated food or drugs in any territory, in the District of Columbia, or in any fort or navy-yard or other place under the exclusive jurisdiction of the general Government. It leaves to each State the matter of regulating the manufacture or sale of adulterated articles within its own borders. The scope of the bill will be found in the abstract of it given in another column.

It is provided in the bill that the National Board of Health shall, from time to time, fix the limits of variability permissible in any article of food, drug, or compound, the standard of which is not fixed by any national pharmacopœia. It will be seen from this proviso, in connection with those in the seventh clause of the bill, that the National Board of Health is to fix the standard of composition in cases where this is not done by the pharmacopœia, and that the operation of the law is made as it were tentative, and given a certain amount of elasticity by avoiding the fixing of details and leaving them to be changed by the Board as circumstances require. This is still further provided for by section 5 of the bill.

The first question to be considered in regard to this proposed legislation is, is there sufficient need for it? It certainly seems to us that there is. The investigations made under the direction of various Boards of Health, State and National, show that the art of adulteration, and selling things under false names, is practised to a very large extent. So far as food is concerned, this matter is of more importance to honest dealers and manufacturers who have to compete with adulterated goods, and to contend in foreign markets against the bad reputation of our products produced by such adulterations, than it is from a sanitary point of view. But so far as relates to the adulteration of drugs, all physicians know the uncertainty of their prescriptions depending upon the uncertainty of the strength and purity of the materials used in compounding them. The evil has long been recognized, and is on the increase. It is true that in our large cities, through the organization of pharmacists, much has been done to remedy it, and that the physicians in such cities can always obtain reliable preparations by selecting his apothecary; but it is also true that a vast amount of weak, impure, and adulterated drugs is annually disposed of in this country upon physicians' prescriptions, and that the results from this are sometimes dangerous—the more so because they are often the unsuspected cause of failure to secure the hoped-for results from remedies ordered. Nor does it seem to us probable that this matter can be corrected by State laws alone, although undoubtedly these are also necessary.

Granting the necessity for a United States law, the bill we have described seems well calculated to secure its purpose. There must be some authority to fix the standards of purity and to exercise discretion, so that there shall be no unnecessary interference with legitimate industry. The National Board, with the aid of the expert advice which it would call in, seems the best authority available for the purpose; it would act with a due sense of responsibility, and may, we believe, be trusted to proceed cautiously and tentatively in the matter. It is not probable that the law will be found satisfactory in all particulars; but, at all events, it will be in the

power of the Board to prevent it from doing harm until the changes which experience may show to be necessary shall have been made.

ANIMAL VACCINATION.

IT has been stated that the protection afforded by vaccination against small-pox is much less complete in recent years than it was in the days of Jenner. Prof. Cameron, of Dublin, has recently called attention to the fact that, in the epidemics of Rotterdam, Montpelier, and Edinburgh, occurring between 1818–23, the mortality among a large number of vaccinated persons attacked was only about 1 in 330 cases; while among the many cases treated in the London hospitals during the epidemics of 1870–79, 1 in every 10 of the vaccinated died. So, also, in the epidemics in the United States in the years 1871–73, the results of the operation were not as satisfactory as might have been expected, although animal vaccination was then beginning to be practised to a very considerable extent. A careful analysis, made by Prof. Cameron, of over 15,000 cases recorded in London in 1852–67, and at periods between 1871 and 1879, shows a marked falling off in the protective power of vaccination, *as measured by the death-rate*. This falling off in the results has been attributed by the advocates of animal vaccination to the deterioration of humanized virus by transmission through a countless number of subjects. The virus is thought to have become attenuated to a degree that has deprived it of much of its original protective influence. To remedy this assumed defect, and restore to the operation the fullest measure of efficiency, it would seem most natural and judicious to return to the original source of the virus, and substitute animal vaccination for the method hitherto almost universally employed, unless provided with virus from lymph or crusts possessing unquestionably the characteristics of true Jennerian virus.

Another reason, of some weight, for the practice of animal vaccination, is to avoid all possibility of transmitting human disease, though authenticated cases of this means of infection are excessively rare.

Animal vaccination is now practised very generally in the United States, but the results of the innovation are not altogether satisfactory. The fault is not with the system, but in its practical application. "Pure and unadulterated" animal virus, judiciously introduced into the system, must confer every possible protection. But the virus supplied from the numerous vaccine farms throughout the country is so often inert or impure from admixture with blood, pus, or other foreign substances, the result of careless or reckless manner of collection and preparation, or, if originally unobjectionable, the uncertainty of its activity when it arrives in the hands of the physician, is so great that confidence in its reliability is apt to be shaken. Resort should, therefore, be made, whenever possible, to virus but few removes from the calf, as being more trustworthy and reliable.

To prevent failure, and to obviate this growing distrust, it would appear incumbent upon the Government or State authorities to organize vaccine farms under their immediate supervision, and this office might, with propriety, be assigned to the National or State Boards of Health. From these sources, a reliable and adequate supply of material could be obtained at all times. If this method were pursued, every possible objection to animal vaccination would disappear, and its advantages would be more universally recognized and applied. The danger of inoculation of human disease, though hardly possible where proper prudence and care are observed, is entirely avoided by the use of bovine virus. A more complete confidence in the operation is established, as is indicated by the greater willingness of the public to have vaccination performed when it is used. Then, again, there need never be any scarcity of supply, as so frequently happens when depending entirely upon the humanized stock.

THE LESSON OF MEMPHIS.

IN another column appears a letter from Dr. R. B. Maury, entitled "Memphis — its Sewers and its Health," which is of much more than local interest. It will be remembered that immediately after the end of the yellow-fever epidemic of 1879 a sanitary survey was made of the city of Memphis, under the auspices of the National Board of Health, by a Commission composed of Drs. Billings, Mitchell, and Folsom, Major Benvaurd, U. S. Engineers, and Col. George E. Waring. This Commission advised a change in the source of supply for the water-works; the introduction of a system of sewerage to discharge into the Mississippi River; a system of subsoil drainage; the keeping the bayous free from contamination; the condemnation and destruction of certain buildings, etc. The system of sewerage has been introduced, but it does not discharge into the Mississippi; it has been turned into Wolf River a few hundred yards below the water-works. The bayous have not only not been kept free from filth, but the sewers have been allowed to overflow into them. Only such subsoil drainage has been introduced as was immediately connected with the sewers laid — an amount altogether insufficient, as Dr. Maury remarks, to secure good drainage. And the source of the water supply has not only not been changed, but fresh sources of impurity have been brought to it by the sewers. It is not to be wondered at that the mortality has rather increased than diminished; that the deaths from dysentery have doubled, and that the death-rate from consumption

is higher than it is on the bleak New England coast; on the contrary, it is rather surprising that the mortality has not been greater. The system of water supply of a city, and its sewerage, are two factors which must be considered together. To bring water in large amount into a city, and make no provision for its removal by sewers after it has been fouled by use, brings on soil pollution; to provide sewerage without an adequate water supply, or without the arrangements necessary to prevent deposits, is to establish a manufactory of offensive and dangerous gases; and to so arrange matters that the sewage, after having been conducted out of the city, shall contaminate its water supply, is certain, in the long run, to produce disease.

Moreover, in a city like Memphis drainage is quite as important a matter as sewerage, and we do not think that Dr. Maury puts the case too strongly when he says that "*we may not reasonably look for much improvement in our death-rate until our drainage is radically improved.*" We would add to this that ventilation must be provided under houses. If they are built without cellars or ventilation, the floors being but a few inches above the damp earth, as is the case with many dwellings in Memphis and New Orleans, it will not be possible to reduce the death-rates from consumption and other forms of lung disease to the point which they ought to occupy in those climates. And this matter of soil-drainage is one that must be carefully considered in deciding on the merits of the small water-tight pipe system of sewers. We believe that for many places this system is an excellent one, *if a drainage system is provided with it*, but the case of Memphis shows that there is great danger that it will not be provided.

We hope that other cities will heed the warning, and that the authorities of Memphis will go on and properly complete their work, and thus prove by actual trial the wisdom of the advice given them by their sanitary commission two years ago.

NAPELINE.

The remarkable properties of aconite, as a remedy for the inflammatory state, as an anodyne, etc., are not possessed in their entirety by the alkaloid aconitine. The explanation of this variation is obvious. Aconite contains several kinds of aconitine—crystallized and amorphous, and *pseudo-aconitine*, which also exists in the two forms, crystallized and amorphous. The aconitine of commerce varies much in purity, the most highly esteemed being Morson's and Duquesnel's. In 1857, Hübschmann discovered in the root of aconitum napellus a new alkaloid, which he named *napelline*. Recently Duquesnel has isolated an alkaloid from the same source, which he designates *napeline*. It is probably the same as that discovered by Hübschmann, one *l* being omitted to give variety. Duquesnel's napeline has been lately studied by Laborde, who has conducted an experimental and clinical investigation. He finds that this new alkaloid differs in many respects from aconitine: it is less active, and has more decided hypnotic and calmative properties. Napeline causes quiet and profound sleep, similar to that caused by narceine. The first trial of it in man was in the case of a neuropathic individual, fifty years of age, attacked with neuralgia, which resisted all the well-known anodynes and antineuralgics. A decided soporific effect was produced by two doses of three and four centigrammes respectively ($\frac{1}{3}$ and $\frac{2}{3}$ grains), and there were no unpleasant after-effects. M. Dumontpallier has used *napelline* with success at Pitie in three cases of neuralgia—one of sciatica, one of facial neuralgia, and one of wandering neuralgia. Laborde finds that this remedy is indicated in neuralgia, persistent insomnia, and in general hyperexcitability of the nervous system. If it be found on further trials to possess the virtues claimed for it by M. Laborde, it will take place amongst our most valuable remedies, and afford another conclusive reason for the belief in the utility of aconite.

BEEF-TEA A STIMULANT, AND NOT A FOOD.

Notwithstanding it has been repeatedly shown that beef-tea is not a food, the laity, and to a considerable extent the profession, are slow to be convinced. That patients fed on beef-tea slowly starve is a fact, which the analysis only too conclusively supports, and which is sustained by accurate clinical observation. In the *Lancet* for October, 1880, p. 562, Mr. G. F. Masterman publishes an analysis, which shows that beef-tea has a chemical composition similar to urine. Beef-tea, most carefully prepared, says Dr. Neale in a recent issue of the *Practitioner* (November, 1881), does not contain, including alkaline salts, more than from 1.5 to 2.25 per cent. of solid matters, and such matter is mainly composed of urea, kreatin, kreatinin, isolin, and decomposed hæmatin. As a stimulant, beef-tea may be, and often is, highly serviceable, but as a means of support during the exhausting drain of a long illness, it does not compare in nutritive value to milk. Dr. Lauder Brunton raises the question whether beef-tea, a product of muscular waste, may not under some circumstances be actually poisonous!

THE SALICYLATES IN RHEUMATISM.

Statistics, to show the exact value of the salicylates as remedies in rheumatism, continue to appear in the English medical periodicals. In our last issue we referred to the paper of Dr. Hood in the *Lancet* of December 31, 1881, in which were tabulated twelve hundred cases of rheumatism, treated with

and without the salicylates, in Guy's Hospital. In the issues of the *Lancet* for January 7 and 14, 1882, there appears a statistical report from Dr. Sidney Coupland of cases of rheumatism treated in the Middlesex Hospital with salicylate of soda. The conclusions derived from an examination of these tables agree in the main with those heretofore published. Dr. Coupland finds that in the majority of cases salicylates speedily reduce fever and diminish the articular pains. Unless the remedy is continued for some time after the subsidence of the fever and pain, relapses will occur. All the reports agree that relapses are apt to take place even when the salicylates are kept up, and may be occasioned by indiscretions on the part of the patient. It is agreed also that these remedies do not prevent cardiac complications. Their actual value consists in the relief which they afford to the pain and fever, but they do not materially lessen the period of confinement necessary. Toxic symptoms are produced by them in a small proportion of the cases.

In the same issue of the *Lancet* we find some remarks of Dr. Maclagan on the administration of salicin and salicylates. He is the apostle of salicin, as our readers have been informed. He maintains that this is superior to the others because it has no injurious effect—a matter of much importance since this remedy must be used in the maximum doses. "Salicin is equally powerful as an anti-rheumatic, but it produces none of the deleterious effects of the salicylates," says Dr. Maclagan. Amongst the "disastrous effects" charged to the action of the salicylates are, according to Maclagan, "delirium, insanity, prostration of the vital powers, syncope, and even death." We need now some satisfactory evidence as to the value of salicin. This is in part afforded by Dr. Maclagan, who appends a report from thirty-nine hospitals of Great Britain. In most of these salicylates are used, but in the Glasgow Royal Infirmary, Glasgow Western Infirmary, and in the Dundee Infirmary, salicin is preferred. In the first named, the report from Prof. Charteris is that salicin and salicylates are "invariably satisfactory," but "preference is given to salicin over salicylates." In the second, the report by Prof. Gairdner is, "have always favored salicin as *versus* salicylates. Have not found it produce any unfavorable symptoms." In the third, the report from Dr. Maclagan says, "salicylates often caused gastric and cerebral disturbance; salicin produced no unfavorable results, and was equally potent."

As salicin is insoluble in water, and must be given in large doses, the question of administration becomes important. Doubtless, the best method is to enclose the powder in capsules, but it may be suspended in mucilage.

ENGLISH PIRACY.

IN our youth we remember the story of a pious preacher who with even perspiring zeal used to give the fiercest thwacks to the ancient Jews, going even so far as to "name" not a few like Ahab and Jezebel, but he was most tender and judicious in avoiding all allusion to the wicked deeds of the merchant princes and speculators who atoned for the sins of six days on 'Change by hanging on his eloquent lips on the seventh.

Our esteemed contemporary, the *Lancet*, seems to have somewhat of the same wise discernment in perceiving sins three thousand miles away, while it is blind to those which exist at its elbow. In the issue of January 7, it begins an article thus, "We have so often protested against the disgraceful practice of pirating English medical books by American publishers and editors, etc." Now it so happens that in the most flagrant case of English piracy of American books that we wot of, the *Lancet* was dumb, and further, although the attention of the editor was specifically called to the matter, he neither published the letter nor alluded to the fact. The "American Health Primers" were published two years ago in Philadelphia. Six of the twelve were republished by Ward & Lock, of London, under the new title of their "Long Life Series." Not only was no honorarium ever offered to the authors (as respectable American publishers usually do in the case of English authors), but their *names were actually erased from the title-pages*. Nay, more; the text was most carefully "edited" so as to cut out everything indicative of their American origin, and the series purported to be "written and edited by distinguished members of the medical profession," which, of course, would mean in England that they were of English origin. In our issue for December, 1880, we called attention editorially to the fraud practised on men like H. C. Wood, Burnett, Cohen, Richardson, Harlan, and White, yet the *Lancet* had no word of condemnation, and even a letter and a copy of one of the pirated books failed to disturb its equanimity.

Not long since the *Edinburgh Medical Journal* exposed the piracy of Dr. G. R. Cutter's *Dictionary of German Terms used in Medicine*, by Dr. Fancourt Barnes, of London, yet the *Lancet* had no "protest," such as its present zeal would suggest would have been at least consistent as well as eminently just.

THE NEW YORK STATE MEDICAL SOCIETY.

THE seventy-sixth annual meeting of this Society began at Albany on Tuesday, under the Presidency of Dr. Abraham Jacobi, of New York City. In another column we give a detailed account of the interesting proceedings, including full abstracts of the scientific papers and the discussions they elicited,

received by telegraph from our special reporter. We have also the pleasure of laying before our readers, in full, the valuable practical papers read at the meeting by Drs. Austin Flint and D. B. St. John Roosa.

We regret to be called upon to record the adoption of the proposed Code of Ethics, which permits consultations with irregular, but licensed, practitioners;—action which severs the affiliation of the Society with the American Medical Association, and which will prove, we fear, far-reaching in its pernicious influence.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Seventy-sixth Annual Meeting, held in Albany, February 7, 8, and 9, 1882.

(*By Telegraph, from our Special Reporter.*)

TUESDAY, FEBRUARY 7.—MORNING SESSION.

The Society met in the Geological and Agricultural Hall, and was called to order at 10 o'clock, by the President, Dr. ABRAHAM JACOBI, of New York, and the session was formally opened by religious exercises, by the Right Reverend Bishop DOANE, who read a portion of the Scriptures and offered a prayer.

The PRESIDENT then delivered his

INAUGURAL ADDRESS.

Dr. JACOBI referred to the status of medical science at the time when the Society was organized, seventy-five years ago, when Bichat first thought of establishing on a sound basis a pathology of the tissues—the period of schools and systems in medicine—in contrast with the present, when cellular pathology reigns supreme, and scientific methods prevail in medical science. In the various stages of progress, this Society has participated, and occupied an honorable position. The elevation of American medicine is due largely to the attainments of the general profession. There is no country in the world but ours, in which the professor and the practitioner are so near kin; the professor, almost always a practitioner, having been selected from the ranks of the profession. After speaking of the parts played by each, he stated that it has not always been on the part of the colleges what the profession understands by progress. In regard to the colleges, it may be stated that their requirements for graduation are certainly not always equally strict. We need not inquire into the reason for the inequality of level, be they pecuniary, intellectual, or other. But the fact is recognized, and nobody is more sorry for it than the profession. In the interest of the public, medical education ought to be of the most advanced kind; health and life claim the protection of the community. That these into whose hands the most important and sacred interests of the people are given, should owe their commission to a corporation of professors, with whose very instalment the community has nothing to do, appears preposterous. Thus the profession has for many years insisted upon a change in the law which licenses practitioners of medicine, and this is growing stronger day by day. Perhaps it cannot be said that the medical schools ever opposed the establishment of a State Board of Examination, which alone would be authorized to convey the license to practise, the right of the colleges to confer diplomas, notwithstanding. If it ever did, it is not probable that any college would now oppose any such movement, which I hope will be set on foot, and result in the Legislature passing a proper law. For the good colleges would not be afraid of their graduates not passing the State Board, and no college would be willing to thwart the movement for fear lest its unwillingness to compete might be recognized as, or alleged to be, the result of incompetency.

The question of affiliation with practitioners legally qualified, but not usually classed as regulars, was taken up and a favorable verdict given. It is asserted by many that the time was coming for abolishing the boundaries between the different classes of medical men. "I do not speak of schools of medical men, for modern medicine is not divided into schools. Moreover, as I have said, the homœopaths claim that they do not differ from us, do not mean to differ from us, as formerly they did, and proudly claimed to do. If we have reason to believe not only that medical science is one and indivisible, and based on logic and experimentation, but that we, the profession of the State of New York, are sufficiently imbued with that spirit of logic and experimental science, we may overlook differences, and meet with a spirit of reconciliation those who do not encounter us any more with the dicta of a school—a sect—but who claim that each individual man amongst them stands on his feet and does his own thinking. A crowd of men, favoring the profession with a battle-cry of '*similia similibus*' and 'no quarter,' exclude themselves, and cannot expect kind treatment at our hands. When the ranks, however, are dissolved, and no *corps d'esprit* raises the flag of hostility, and instead of a fighting army under orders, men come into your camp for reconciliation and a parley, the case is different. Besides, in the effort to better the condition of the profession and the public, it is better that no part of the legally qualified practitioners should be excluded from the benefit of such efforts, or from co-operating in that direction."

The question of preventible disease was taken up at some length and discussed, with especial reference to the necessity of providing hospitals for proper treatment of children suffering with contagious disorders, especially scarlatina and diphtheria, in all large cities. Such isolation and intelligent care is needed, not only for the poor, but also for the rich, in order to prevent the spread of these diseases. A letter written by the Secretary of the Society for the Prevention of Cruelty to Children, addressed to the Mayor of New York, illustrating the great need existing in that city, was quoted, and Dr. Jacobi announced that pecuniary aid had been promised for the establishment of such an institution in New York City.

In conclusion, attention was directed to the want of legislation to protect factory children in New York State, and it is recommended that (1) Children employed in factories should be under official supervision. In large cities the Boards of Health could be entrusted with this task. (2) Before being admitted to factory work a child of legal age ought to undergo a medical examination, and chlorotic, anæmic, scrofulous, crippled, scoliotic, bronchitic, and phthisical children, and those under the normal size for their age should be excluded. (3) No night or Sunday work ought to be permitted. (4) Some branches of work to be forbidden entirely, such as mining, glassworks, rag-sorting, working in mercury, lead, arsenic, etc., and in match factories. (5) The earliest age at which the young ought to be admitted to manufacturing employments ought to be fourteen years. Up to the period of puberty the energies of life and mind needed in the development of the individual should not be wasted recklessly.

Dr. Jacobi concluded his address with personal reminiscences, and a comparison between his position on his arrival in this country, twenty-eight years ago, upon exit from a political prison, and the position he now

occupied, the honors of which had been conferred upon him unsolicited by the Society.

The recommendations contained in the President's address were referred to a special committee to be subsequently appointed.

The President then announced the appointment of the following

COMMITTEES.

Business Committee.—Drs. D. B. St. John Roosa, of New York; W. S. Ely, of Rochester; and C. R. Lee, of Oswego Co.

Committee on Credentials.—Drs. Robert Frazier, of Oneida Co.; F. R. Bentley, of Ontario Co.; and William Taylor, of Madison Co.

A recess of ten minutes for registration was then taken.

After the recess the following gentlemen present were made

MEMBERS BY INVITATION.

Drs. E. C. Seguin, of New York; John B. Stonehouse, Wm. Geoghegan, Theo. P. Bailey, G. B. Tefft, Lewis Balch, all of Albany; Lucius E. Felton, of Potsdam,; Brayton Babcock, of Allegheny Co.; S. O. Vanderpoel, Jr., John F. Lockwood, H. R. Starkweather, S. R. Morrow, Chas. F. Huddleston, Lorenzo Hale, John Thompson, W. J. Nellis, all of Albany; Samuel Peters, of Cohoes; A. B. Huested, Otto Ritzmann, P. J. Keegan, and J. W. Gould, all of Albany.

Following the report of the Business Committee, was a report from the Special Committee appointed at the last meeting, to revise the Code of Ethics. By request of this Committee the Business Committee was directed to set apart a special evening for the discussion of the report, and Tuesday was appointed. The following draft of a Code of Medical Ethics was then presented by the Committee (consisting of Drs. Wm. C. Wey, C. R. Agnew, S. Oakley Vanderpoel, Wm. S. Ely, and Henry G. Piffard).

CODE OF MEDICAL ETHICS.

I. *The Relations of Physicians to the Public.*—It is derogatory to the dignity and interests of the profession for physicians to resort to public advertisements, private cards, or handbills, inviting the attention of individuals affected with particular diseases, publicly offering advice and medicine to the poor without charge, or promising radical cures; or to publish cases or operations in the daily prints, or to suffer such publications to be made; or through the medium of reporters or interviewers, or otherwise, to permit their opinions on medical and surgical questions to appear in the newspapers; to invite laymen to be present at operations; to boast of cures and remedies; to adduce certificates of skill and success, or to perform other similar acts.

It is equally derogatory to professional character, and opposed to the interests of the profession, for a physician to hold a patent for any surgical instrument or medicine, or to prescribe a secret nostrum, whether the invention or discovery or exclusive property of himself or of others.

It is also reprehensible for physicians to give certificates attesting the efficacy of patented medical or surgical appliances, or of patented, copyrighted, or secret medicines, or of proprietary drugs, medicines, wines, mineral waters, health resorts, etc.

II. *Rules Governing Consultations.*—Members of the Medical Society of the State of New York, and of the medical societies in affiliation therewith, may meet in consultation legally qualified practitioners of medicine. Emergencies may occur in which all restrictions should, in the judgment of the practitioner, yield to the demands of humanity.

To promote the interests of the medical profession and of the sick, the following rules should be observed in conducting consultations:

The examination of the patient by the consulting physician should be made in the presence of the attending physician, and during such examination no discussion should take place, nor any remarks as to diagnosis or treatment be made. When the examination is completed, the physicians should retire to a room by themselves, and after a statement by the attending physician, of the history of the case and of his views of its diagnosis and treatment, each of the consulting physicians, beginning with the youngest, should deliver his opinion. If they arrive at an agreement, it will be the duty of the attending physician to announce the result to the patient, or to some responsible member of the family, and to carry out the plan of treatment agreed upon.

If in the consultation there is found to be an essential difference of opinion as to diagnosis or treatment, the case should be presented to the patient, or some responsible member of the family, as plainly and intelligently as possible, to make such choice, or pursue such course as may be thought best.

In cases of acute, dangerous, or obscure illness, the consulting physician should continue his consultation-visits at such intervals as may be deemed necessary by the patient or his friends, by him, or by the attending physician.

The utmost punctuality should be observed in the visits of physicians when they are to hold consultations, but as professional engagements may interfere or delay one of the parties, the physician who first arrives should wait for his associate a reasonable period, after which the consultation should be considered as postponed to a new appointment. If it be the attending physician who is present, he will of course see the patient and prescribe, but if it be the consulting physician, he should retire, except in an emergency, or when he has been called from a considerable distance, in which latter case he may examine the patient and give his opinion in writing, and under seal, to be delivered to his associate.

III. *The Relations of Physicians to each other.*—All practitioners of medicine, their wives, and their children while under paternal care, are entitled to the gratuitous services of any one or more of the faculty residing near them, whose assistance may be desired.

Gratuitous attendance cannot, however, be expected from physicians called from a distance, nor need it be deemed obligatory when opposed by both the circumstances and the preferences of the patient.

The affairs of life, the pursuit of health, and the various accidents and contingencies to which a medical man is peculiarly exposed may require him temporarily to withdraw from his duties to his patients, and to request some of his professional brethren to officiate for him. Compliance with this request is an act of courtesy which should always be performed with the utmost consideration for the interests and character of the family physician, and when exercised for a short period, all the pecuniary obligations for such service should be awarded to him. But if a member of the profession neglect his business in quest of pleasure and amusement, he cannot be considered as entitled to the advantages of the frequent and long-continued exercise of this fraternal courtesy without awarding to the physician who officiates the fees arising from the discharge of his professional duties.

In obstetrical and important surgical cases, which give rise to unusual fatigue, anxiety, and responsibility, it is just that the fees accruing therefrom should be awarded to the physician who officiates.

Diversity of opinion and opposition of interest may, in the medical as in other professions, occasion con-

troversy and even contention. Whenever such cases unfortunately occur, and cannot be immediately terminated, they should be referred to the arbitration of a sufficient number of physicians before appealing to a medical society or the law for settlement.

If medical controversies are brought before the public in newspapers or pamphlets, by contending medical writers, and give rise to, or contain assertions or insinuations injurious to the personal character or professional qualifications of the parties, the effect is to lower in the estimation of the public, not only the parties directly involved, but also the medical profession as a whole. Such publications should, therefore, be brought to the notice of the county socities having jurisdiction, and discipline inflicted, as the case may seem to require.

COMMUNICATIONS FROM COUNTY SOCIETIES.

In the call of reports from County Societies, the New York County Society only, was ready with a report, and offered a communication in regard to medical legislation and medical ethics, which were by request referred to special committees already existing.

THE COMMITTEE ON PRIZE ESSAYS

reported that but one essay had been forwarded, "On Tubercle and Cancer," which was deemed worthy of publication, but did not possess the evidence of original research and high standard of excellence to qualify it for the honor of a prize.

Dr. WILLIAM S. ELY, appointed at the last meeting Censor of the College of Medicine,

SYRACUSE UNIVERSITY,

reported favorably, after examination, as to the qualifications of graduates of that school. The high standard observed was attributed chiefly to its graded course of instruction.

The Business Committee offered a resolution limiting the time of reading papers to twenty minutes, and making all motions to extend the time out of order.

On motion, three meetings were directed to be held daily (9 to 12 M., 3 to 6, and at 8 P.M.)

Scientific papers being called for, Dr. F. R. STURGIS read a paper in connection with the subject of Medical Education (which was made a topic for special discussion at this meeting, by the action of the New York County Society, as presented in their communication to this Society), entitled:

HINTS AND SUGGESTIONS UPON MEDICAL EDUCATION.

After considering the problems as presented at present in this country, Dr. Sturgis recommended the following measures as a step towards their solution:

1. The absolute incorporation of medical schools with some chartered school or university making the governing bodies of both the same.

2. Endow the school liberally for educational purposes and make it independent of the students' fees.

3. Separate the right to practise from the diploma. The latter, then, should be a token of proficiency in study and knowledge, and its possession from some school in good legal and professional standing, should be made obligatory before a candidate can present himself for authority to practise in this State.

The views expressed were earnestly endorsed by Dr. ROOSA, and were further discussed by Dr. PERKINS.

Dr. MOORE, of Rochester, advocated the establishment of an Examining Board under the authority of the State Society, rather than to entrust the interests of the profession to an irresponsible and independent body of persons. The great advance in medical education in this country, from the time of his own graduation and under his own observation in the experience of a single lifetime, was referred to, and a hopeful view taken of medical progress in this country in the future. Referring to the establishment of a Board of Examiners, he said that it would not succeed if hostile to the schools, but having a representative from each of the schools in the Commonwealth, it might establish a system of uniform examination for the medical degree. The standard was stated to be what a young man of average attainments can accomplish in the space of time allotted to him. The expenses of the Board should be borne by the Colleges, and the Board should be kept entirely free from political intrigue and influence. Irregular schools and practitioners ought not to be recognized.

Dr. PIFFARD, of New York, advocated the establishment of a single mixed Board, such as was contemplated by Dr. Sturgis.

Dr. STURGIS, in conclusion, claimed that the establishment of such a Board would place irregulars under some sort of control, and do away with all partisan and sectional feeling, which is now the strongest argument of the quack.

Dr. E. R. SQUIBB, of Brooklyn, read a

NOTE ON CLINICAL THERMOMETERS,

calling attention to the defects of the instruments now in use. Thousands of cheap thermometers are sold annually, which are devoid of the skill and care requisite to make a good instrument. The aim should be to obtain one accurately graded to the range within which it is intended to be used. Besides the ordinary errors due to faults of calibre and length, there is a contraction of the bulb, which, rapid at first, continues more slowly, even for several years. After three years, however, it is insignificant, unless the bulb should be heated. Thermometers should not be graduated immediately after they are made. All thermometers should be seasoned for at least three years before the tubes are graduated. The majority of cheap thermometers give incorrect observations, as do also good instruments which have been graduated too soon. Every clinical thermometer should be accompanied by a Kew certificate, or, in this country, by the certificate of the Observatory of Yale College. The charge is fifty cents for this service, and if a physician has a clinical thermometer with such a certificate of examination after three years' seasoning, he can rely upon having a good instrument for use. Dr. Squibb gave the following requisites for a good instrument:

1. The mercury should not rise too slowly; if it does, the bulb is too thick; if too rapid, the bulb is too thin.

2. If the time required to reach the maximum under the tongue is more than nine minutes, it should be rejected as too slow. It should attain it inside of nine minutes, remaining nearly stationary after five or six minutes. Those attaining the maximum too early are liable to be easily broken.

3. The self-registering thermometer should not have its index shaken down too readily. After the register is joined with the column, the instrument is spoiled. Hick's lens-front thermometer was spoken of favorably. A tube five or six inches in length is preferable to one of four.

For correcting a thermometer Dr. Squibb recommended placing it with a standard thermometer under the tongue, and comparing the maximum readings.

The Business Committee presented

OBITUARY NOTICES

of Drs. Levant B. Coates and John F. Whitbeck, which were referred to the Publication Committee.

By request of several members the Business Committee recommended that the proper section of the By-Laws be suspended in order that the

REPORT OF THE NOMINATING COMMITTEE

should be made at the close of the second day's session instead of deferring it until the third day as before. As

it required unanimous consent, it was lost by Dr. Vanderpoel voting in the negative.

Dr. WILLIAM S. ELY, of Rochester, read a short paper, entitled

NOTE ON BEEF-JUICE.

He advocated its liberal use (4 to 30 ounces per diem). He advised in its preparation the use of the "fruit-press." A pound or two of lean beef is cut in small pieces, and thoroughly heated, but not cooked, over the fire, and then being transferred to the cylinder is expressed, and subsequently strained. It contains the juice of the meat, the albumen being uncoagulated. He used it largely in diphtheria; in one case he gave the juice of nine pounds of meat in twenty-four hours (making twenty-eight ounces of juice). It can be used for rectal alimentation.

Dr. GRAY advocated the addition of some alcohol or claret, in order to preserve the fluid.

The Business Committee announced that the

ANNUAL BANQUET

would be given at the Delavan House, immediately after the delivery of the Annual Address by the President, at the Capitol, on Wednesday evening.

FIRST DAY.—AFTERNOON SESSION.

The Society re-assembled at 3 o'clock.

Dr. S. O. VANDERPOEL read a brief, but interesting and suggestive paper, entitled

THE PRESENT CONDITION OF THE TUBERCULOSIS QUESTION,

which he recapitulated as follows:

1. Pulmonary phthisis is not wholly a blood dyscrasia, resulting in the deposition from the blood of a peculiar element of low vitality, called tubercle; at first, in small gray granules, which aggregate, change their appearance, and become the large cheesy masses so familiar to all. A doctrine elaborated by Laennec, and still maintained by a large proportion of the German school.

2. Nor is it, as taught by Niemeyer, a simple caseous degeneration, but rather is the result of catarrhal inflammation in a scrofulous subject, whether in a bronchial or mediastinal gland, which becomes an infecting focus; as a result, the tubercular element soon appears. This material of low vitality soon undergoes necrotic changes, hastening this process in the general mass. The infecting foci are constantly increased until the lung tissue is largely infiltrated; with the increase in infiltration, there is a corresponding increase in the range of temperature and rapidity of emaciation, the tubercular deposit favors this activity, as we know in cases of pure tubercular phthisis. If, then, by appropriate treatment, hygienic or medicinal, we can exclude it, the chronicity of the case is better assured, and the chances of recovery correspondingly increased. It gives a percentage of hope, where the teachings of half a century have been almost hopeless.

The reading of Dr. Vanderpoel's paper upon tuberculosis led to an interesting discussion upon the pathological characters of consumption.

THE PRESIDENT, being called upon for his views upon the subject, said, in reference to the term scrofula, that the word is generally and legitimately used to express a certain condition, in which we wish to avoid circumlocution. In one individual, an inflammation, following injury of a mucous membrane, goes regularly through certain changes, by proliferation of cells, to the formation of healthy tissue; in another case the proliferation of cells occurs, but instead of forming normal epithelium the cells break down, and, their production continuing, they accumulate without completing the process of repair. A similar process may occur in bone or in a gland; the cells finally undergoing fatty degeneration, "caseation," or softening. When this tendency is discovered, it is common to express the fact by the use of the term scrofula. He believed it entirely unnecessary to refer such a condition to a hypothesis based on the old humoral pathology. In many cases of tuberculosis of the lung, the process is an embolic one. In conclusion, he called attention to the necessary distinction insisted upon by Niemeyer, existing between phthisis and tuberculosis, a distinction which appears to be often ignored in discussions upon the subject at the present time.

POSTURAL TREATMENT OF UTERINE DISEASE.

Dr. W. W. POTTER, of Buffalo, read a communication on the "*Genu-Pectoral Posture in Retro-Displacements of the Uterus and Prolapsus of the Ovaries.*" The conveniences required in knee-chest manipulations are (1) a table on casters; (2) a speculum (Bozeman's preferred); (3) forceps, double curved; (4) cotton pledgets, secured by threads of silk, about the size of a walnut, prepared in advance; (5) pessaries (Albert Smith's) of several sizes, and a few astringent and sedative solutions. The sound is rarely needed in the retro-displacements when treated in this posture. If it be correctly assumed, a right-angled triangle is formed, with the table for its base, the thighs of the patient the perpendicular, and the body the hypothenuse. In some cases the retroverted uterus immediately resumes its normal position; in others, the cotton is packed *in situ* for several days in succession, until more permanent methods of support can be adopted if found necessary.

A biographical sketch of a deceased member, Dr. James P. Boyd, was read by title and referred.

THE NOMINATING COMMITTEE

was selected as follows: from 1st District, Thomas R. Pooley, M.D.; 2d District, J. Foster Jenkins, M.D.; 3d District, Norman L. Snow, M.D.; 4th District, B. F. Sherman, M.D.; 5th District, W. H. Johnson, M.D.; 6th District, C. L. Stiles, M.D.; 7th District, John Gerin, M.D.; 8th District, W. W. Potter, M.D.; Society at large, William C. Wey, M.D.

The following-named visitors were made

MEMBERS BY INVITATION:

Drs. Franklin Townsend, Albany; Ed. H. Squibb, Brooklyn; T. Z. Gibbs, Fort Ann; D. H. Goodwillie, New York.

EXTRAORDINARY BONE DEVELOPMENT.

Dr. E. M. MOORE, of Rochester, exhibited a specimen and reported a "Case of Extraordinary Bone Development," which originally was a dorsal dislocation of the head of the femur, which, after manipulation, was left in the extraordinary position of reversing the head of the femur, so that it pointed anteriorly on the dorsal aspect of the ilium, with the toes pointing outwards; the shortening was over two inches. Anchylosis and immense bony development occuring, subcutaneous division of the femur with a Hey's saw was made by Dr. Moore, and the leg was brought into good position and drawn down, a gap of one and one-half inches being subsequently filled with bone, although a false joint could not be secured. The man was able to walk upon the limb and continue his avocation.

EFFECTUAL DOSAGE OF CERTAIN REMEDIES USED IN THE TREATMENT OF NERVOUS DISEASES,

was the title of a short paper by Dr. E. C. SEGUIN, of New York. He had been led to present this communication from having observed a number of cases, especially of chorea, and cerebral syphilis, or brain tumors, in which practitioners had used the proper remedy, but had failed in the desired result, because they had been

too timid in administering sufficiently large doses. There seems to be a deficiency in medical teaching as to the maximum physiological dose that may be employed in particular cases. He then reviewed posologically a few drugs, giving the doses usually recommended, and the maximum in certain cases of nervous disease, based upon personal experience. He advised beginning with the ordinary doses and pushing them rapidly, in proper cases, to the maximum required by the individual. They are especially considered in reference to their use in nervous diseases. *Nitrate of silver* is commonly employed in doses of one-sixth to one-half grain three times a day, in locomotor ataxia, and various forms of sclerosis especially, and Erb speaks of it very favorably in this class of cases. Dr. Seguin's experience has led him to endorse the views of Erb, and he has used it also in myelitis. He recommends one-quarter to one-half grain to be given thrice daily before meals and continued for several months. He has never seen any cases of argyria resulting.

Duquesnel's Aconitia.—Gublar introduced and highly recommends in trigeminal neuralgia (from $\frac{1}{120}$ to $\frac{1}{124}$ of a grain). His own experience is very favorable (Caswell & Huzard, and Schiefplin & Co., make very reliable tablet and pills of aconitia), he recommends a commencing dose of $\frac{1}{140}$ of a grain, and carefully discovering the amount of susceptibility of the patients. In debilitated and female patients, it is better to begin with $\frac{1}{300}$ or $\frac{1}{250}$ of a grain; after using this for several days without bad effects, the drug may be pushed to $\frac{1}{100}$ of a grain, given three times a day. He had given from four to eight of such doses in cases of ataxia without relieving the pain or causing numbness; he had found it especially valuable in trigeminal neuralgia. *The Fluid-Extract of Conium* (Squibb), has for its usual dose from ♏ij–v.; much larger doses are well borne. [This paper was cut short by the expiration of the time allotted by the Business Committee; it was, on motion, referred to the Publication Committee, the lecturer not being a member of the Society except by invitation.]

Dr. CHASE, of Brooklyn, reported a case of supra-orbital neuralgia, in a lady of eighty years, in which he had given $\frac{1}{75}$ of a grain of aconitia, three times a day (aggregating $\frac{1}{25}$ of a grain in the day). After six or seven days prostration occurred, but no worse result. Dr. Seguin said that he had given as much in aggregate as $\frac{1}{6}$–$\frac{1}{4}$ of a grain in the day; he was not aware of any fatal accident, although some cases of collapse had followed large doses.

Dr. SQUIBB objected to the proprietary flavor of the expression used by the lecturer, of Squibb's conium, as the preparation is simply the fluid-extract of conium prepared according to the U. S. Pharmacopœia of 1860. In connection with the subject of the paper, he remarked that it should be remembered that there is a different susceptibility to drugs and the effects are slightly different in kind in different persons. We must, therefore, be careful in applying general averages to individual cases. The different varieties of aconite furnish different alkaloids, and the Duquesnel's aconite is probably obtained from the aconite of the Himalayas, which is comparatively stronger than our Napellus, and is properly known by the name of the manufacturer.

Dr. SEGUIN, in concluding the debate, mentioned that the doses of conium usually ordered were insufficient; he uses very large doses in proportion, never giving less than gr. xx.–xxxx. to adults; sometimes giving as much as a drachm at a dose, with only good effects in chronic convulsive disorders, especially in chorea of adults. He also uses the conium in doses of gr. xx.–xxx. as an indirect hypnotic, especially in combination with bromide of potassium.

Dr. SQUIBB, by permission, warned against the danger of diluting the conium fluid-extract—of a precipitate being formed, the active principle may be deposited and thus be given in a comparatively large dose at the end. He knew of bad results, but of no fatal accidents from this cause.

Dr. CHARLES S. BULL read an essay on

SYPHILITIC DISEASES OF THE LACHRYMAL APPARATUS.

The specific lesions of these associated organs are rare; when affecting the tear-gland, the parenchyma is invaded, but the sac usually escapes injury. Two cases of syphilitic disease of the caruncle, occurring in the practice of Dr. Post, of New York, were reported, the form of disease being gummy infiltration. Papular and tubercular syphilis may occur on the lids, and extend to the canaliculus, and into the sac. More commonly the disease commences in the nose, and subsequently causes dacryo-cystitis. The orifice of the nasal duct may be obstructed by a mucous patch it its neighborhood, or by a gummy deposit. The obstruction usually begins near the opening of the duct, but subsequently the disease and resulting stricture may involve the entire length of the duct. Epiphora, and dacryo-cystitis, and abscess, with subsequent fistula, may result, but not very commonly, from syphilis. The tendency of syphilitic lesions of the lachrymal apparatus is destructive, unless properly and promptly treated. Necrosis and sequestration of the bony portion of the lachrymo-nasal canal is a secondary process likely to occur; also periostitis followed by exostosis, and, perhaps, caries and obliteration of the nasal duct. Especially is this process likely to commence in the ascending apophysis of the superior maxillary bone. Medical treatment of these cases, in preference to surgical interference, is considered to be of advantage to the patient. Surgeons should not hastily slit up the canaliculus in cases of syphilitic disease of the eye.

Dr. LUCIUS E. FELTON, of Potsdam, presented a model of a

NEW GALVANIC BATTERY.

In this battery the carbons are cylindrical, and about three inches in length. In order to prevent the corrosion of connections the end of the carbon is covered with copper, and a metal plug is then driven into a hole bored for the purpose. The carbon is next dipped in melted paraffine, the exposed portion is then coated with marine glue, which perfectly protects the connection. The zincs are united in sections, so that those not in use need not be immersed in the fluid. The cells are absolutely water-tight, so that no fluid escapes if the battery is turned over. The electro-motor force is a little over two Volts. for each cell. It is a simple bichromate and acid battery with zinc and carbon elements. The one exhibited contained eighteen cells.

The apparatus was commended by those who examined it, and considered an improvement over the ordinary form of constant current batteries.

FIRST DAY.—EVENING SESSION.

The meeting was called to order at 8 o'clock, and the consideration of the report of the Committee on the

CODE OF ETHICS,

which was made the special order for this evening, was discussed. Inasmuch as the proposed new Code of Ethics contemplated such an innovation as permitting consultation with irregular practitioners, it naturally called forth general expression of opinion, which, to a great extent, was adverse to it.

Dr. ROOSA, of New York, as a substitute to the report of the special committee, offered the following:

"The Medical Society of the State of New York, in view of the apparent sentiment of the profession connected with it, hereby adopts the following declaration, to take the place of the formal Code of Ethics, which has,

up to this time, been the standard of the profession in this State.

"With no idea of lowering, in any manner, the standard of right and honor in the relations of the physicians to the public and to each other, but, on the contrary, in the belief that a larger amount of discretion and liberty in individual action, and the abolition of detailed and specific rules, will elevate the ethics of the profession, the medical profession of the State of New York, as here represented, hereby resolve and declare,

"That the only ethical offences for which they claim the province to exercise the right to discipline, are those comprehended under the commission of acts unworthy a physician and a gentleman.

"*Resolved, also*, That we enjoin the County Societies, and other organizations in affiliation with us, that they strictly enforce the requirements of this code."

The substitute received thirty-nine yeas and thirty-seven nays. The President ruled, however, that it was an amendment to the By-laws, and required a two-thirds vote, and, therefore, he declared it lost.

The report of the Committee (see page 161) was finally adopted by a two-thirds vote, after the entire evening had been devoted to its discussion.

WEDNESDAY, SECOND DAY.—MORNING SESSION.

Meeting was opened by prayer at 10 o'clock—Dr. WILLIAM GOVAN, Vice-President, in the chair.

The following gentlemen were made

MEMBERS BY INVITATION:

Drs. S. G. Delamater, of Duanesburg; J. P. Creveling, of Auburn; J. F. Fox, of Cohoes, and J. Ennis, of Schenectady.

THE COMMITTEE ON BY-LAWS

reported having made an examination of the proposed alterations in the By-laws of Rockland, Greene, Fulton, and New York Counties, and finding them in accordance with the laws of the State of New York, and of the By-laws of this Society, recommend their approval. The report was adopted.

The Committee also reported that only six County societies were operating under by-laws in accordance with the laws of the Society, and urged other societies to present their by-laws to the State Society for revision according to law.

Dr. PERKINS, of Schenectady, offered a resolution directing a committee to be appointed to make arrangements for the

CORRECTION OF CLINICAL THERMOMETERS

by the Dudley Observatory, at Albany, on the plan pursued by the Winchester Observatory, of Yale.

This motion was opposed by Dr. Squibb, and he urged that Yale Observatory had been well equipped, at considerable expense, and was now able to examine all the clinical thermometers in the country, and at a very reasonable charge. The motion was accordingly lost.

The following

AMENDMENT TO THE CONSTITUTION

was proposed by Dr. Roosa, of New York, and laid over, under the rule, for one year:

"Offences against the ethics of this Society are only to be comprised under the head of acts unworthy of a physician and a gentleman."

REPORT OF THE TREASURER.

The Treasurer, Dr. CHARLES H. PORTER, of Albany, made his annual report, showing a balance in the treasury of $453. The accounts were audited and approved.

THE COMMITTEE ON HYGIENE,

Dr. E. V. STODDARD, of Rochester, Chairman, made a verbal report of progress, and asked permission to present the formal report to the Secretary for publication in the proceedings.

THE COMMITTEE ON EXPERIMENTAL MEDICINE

reported, through its Chairman, Dr. JOHN G. CURTIS, of New York, that a bill presented by Mr. Bergh to the State Legislature, preventing vivisection, had failed to pass, chiefly owing to the efforts of this committee.

The report concluded with the following resolutions, which were adopted:

Resolved, By the Medical Society of the State of New York—

I. That it is the unanimous opinion of the members of this Society, that the unrestricted performance by qualified medical men of scientific experiments upon animals, is essential to the maintenance and progress of the science and art of medicine.

II. That while the Society would thus set forth to the Senators and Assemblymen, in Legislature assembled, the views of the medical profession of the State upon this subject, it would also call their attention to the fact that at the late International Medical Congress in London, a formal resolution, denouncing interference with experimentation upon animals, was adopted by more than three thousand official representatives of the medical profession of the world.

III. That in the event of the introduction of any so-called "anti-vivisection bill" into the Legislature of 1882, it shall be the duty of the Committee on Experimental Medicine to forward a certified copy of these resolutions, as a memorial from this Society, to the Governor of the State of New York, and to each house of the Legislature thereof.

On motion of Dr. AGNEW, of New York, it was directed that the foregoing resolutions be printed and distributed among the members of the Legislature.

THE COMMITTEE ON LEGISLATION

reported, through its Chairman, Dr. Albert Vanderveer, of Albany, in regard to the communication from the County Society of New York, containing drafts of amendments to two laws regulating the practise of medicine in this State. The first amendment provides that

"The Regents of the University of the State of New York shall appoint one or more boards of examiners in medicine, each board to consist of not less than seven members, who shall have been licensed to practise physic and surgery in this State; and all persons desiring to practise physic or surgery, after the passage of this act, must submit to the examination hereinafter provided, and obtain the diploma hereinafter provided, before entering upon the practise of physic or surgery in this State."

The second amendment is intended to remedy the defects discovered in the Act of 1880, "to regulate the licensing of physicians and surgeons."

On motion, the above recommendations were directed to be printed and distributed among the members, and made the special order of business for Thursday.

Dr. DANIEL LEWIS, of New York, read a paper on

THE TREATMENT OF SCARLATINA,

in which, following the recommendation of Prof. Bartholow, in his Cartwright lecture on the antagonism of drugs to disease, he had adopted the treatment of scarlitina by digitalis in full doses. He commended the use of the infusion of the fresh leaves, given in drachm-doses three or four times a day, to children (from three years up). The only other treatment was by local application of glycerin diluted, with tincture of chloride of iron and chlorate of potassium, during convalescence. The results of one hundred and fifty cases were given in this communication, out of which only seventeen died. There were only two cases of otitis in the entire number, and

both were mild ones. No cases occurred of suppuration of the cervical glands.

Dr. LARENZO HALE, of Albany, presented an essay on

AN IMPROVED DRESSING FOR FRACTURED CLAVICLE,

in which he recommended a modification of Moore's dressing; the principal feature of this new method consisted of an adjustable back-sling made of a suspender-brace, being tightened during the day, and allowed to be more lax during the night.

Dr. VANDERVEER spoke in approval of this dressing from personal experience.

Dr. H. KNAPP, of New York, read a paper

ON CROUP OF THE CONJUNCTIVA, WITH REMARKS ON CONTAGIOUS FORMS OF CONJUNCTIVAL INFLAMMATION.

From observation of two unusual cases occurring in children, he announced that he had been obliged to change a previously-held opinion, and was led to recognize an important difference between the morbid anatomy of croupous and diphtheritic inflammation, and important differences between the course of the two diseases when affecting the structures of the organs of vision. He concluded with some remarks upon the value of the methodical application of cold to communicable conjunctival disorders, especially by light ice compresses, continued until the tumefaction of the lids and the thickness of the discharge is reduced. This treatment is capable of saving all cases of ophthalmia neonatorum, and nearly all cases of conjunctival diphtheria.

Dr. C. R. AGNEW, of New York, read a paper upon

COMMUNICABLE EYE DISEASE, AND SOME OF ITS RELATIONS TO BLINDNESS AND PAUPERISM,

and urged greater attention to the hygiene of children's homes, especially as regards cleanliness in lavatories, breathing space in sleeping apartments, and abundance of milk in the diet.

The two preceding papers were discussed together, the members generally speaking in slighting terms of the use of antiseptics *per se*, and insisting upon the importance of systematic cleanliness, cold applications, and good general hygiene. The use of water slightly impregnated with neutral salts, such as sodium chloride, and saturated solution of boracic acid, were generally recommended in preference to more active treatment on the one hand, or simple water dressings upon the other. In using cold, the prevalent "slop-water application" was condemned, as keeping the patient wet and uncomfortable; and because he had seen secondary inflammation of the auditory meatus caused in several cases by the water washing the secretions down into the ear. The plan preferred was by placing a block of ice at the bedside, the cloths being laid upon it, and frequently renewed; another plan was to fill a small rubber bag with snow, or pounded ice, and keep it applied as before.

INTERNAL ŒSOPHAGOTOMY.

Dr. JOHN O. ROE, of Rochester, read the history of a case of a lady who suffered with difficulty in swallowing for several months without assignable cause. Dr. Roe diagnosticated stricture of the œsophagus, although no permanent organic narrowing existed. Internal œsophagotomy, after the plan of Morell Mackenzie, of London, was proposed and practised, followed by rapid and complete recovery.

SECOND DAY.—AFTERNOON SESSION.

In the discussion upon Dr. Roe's paper two unpublished cases of internal œsophagotomy, with successful results, were mentioned by Dr. ELSBERG. He warned the Society that the operation should not be done except in great emergency, and even then only with the greatest care to prevent serious injury.

Dr. POST, of New York, desired to correct the possible impression which might be received from the paper, that a person suffering with œsophageal stricture must necessarily starve to death, and that the operation is the only alternative. Rectal alimentation will keep the patient alive for an indefinite period.

Dr. LOUIS ELSBERG read a paper on

THE MUSCLES OF THE LARYNX AND THE LARYNGOSCOPIC IMAGES PRODUCED BY THEIR PARALYSIS.

If, in affections of either the brain or the pneumogastric or the recurrent laryngeal nerve, all the laryngeal muscles on either or on both sides are paralyzed, the corresponding vocal bands, of course, assume a position uninfluenced by muscular action, *i. e.*, like the cadaveric position. When they are fixed in this position, either on one side or on both, during attempts at phonation, as well as during respiration, the appearance is very characteristic, and easily recognized by means of the laryngoscope, so that the diagnosis is clear and conclusive. In such a case there is no real difficulty of breathing, but a good deal of *leakage of air*, as I call it, and therefore a waste of breath. The voice is weak, or else reduced to an almost inaudible whisper. The patient cannot cough, expectorate, or speak properly, because in these acts it is necessary to close the *rima glottidis*; and this he cannot do. Speaking, of course, requires a greater effort, the muscles of expiration (especially the abdominal) are unusually strained; therefore, discomfort is felt, and quickly, fatigue. On forced inspiration, a stridulous sound is often produced, which comes from the air passing through the upper aperture of the larynx and the flaccid vocal bands.

But when the paralysis, whether bi-lateral or unilateral, *is* or *becomes incomplete*, a very curious, and as yet unexplained, fact has been observed, which is of very great importance for general medical practitioners, as well as for specialists, to know; it is the fact that the abductor filaments (those that separate the vocal bands) are more prone to be affected than the adductor filaments (those that shut up the breathing space), and that if in a disease in which both the abductors and the adductors are affected, *recovery* takes place, the adductors are apt to recover first, or exclusively; so that in such a case a patient *during the progress of recovery* is in danger of a dyspnœa, which may necessitate tracheotomy to prevent death.

Paralysis of the narrowers of the rima glottidis causes, during attempted phonation, more or less leakage of air, and gives its characteristic image during that act; while paralysis of the wideners of the rima glottidis causes more or less dyspnœa, and must be examined for its characteristic image during inspiration and expiration. The first causes phonatory leakage, the second respiratory insufficiency.

Dr. WILLIAM HAILES, Jr., of Albany, presented a communication upon *Improved Methods in Laboratory Teaching and Demonstrations in Histology*.

Dr. AUSTIN FLINT read a paper upon

THE PHYSICAL DIAGNOSIS, BY MEANS OF PERCUSSION AND EXPLORATION BY PUNCTURE, OF PERITONITIS WITH AND WITHOUT PERFORATION OF THE ALIMENTARY CANAL, AND THE EMPLOYMENT OF ASPIRATION IN CASES OF PERFORATING PERITONITIS. (See p. 149.)

TREATMENT OF DOUBLE TALIPES EQUINO-VARUS.

Dr. A. M. PHELPS, of Chateaugay, reported eight cases treated by free incision and extension. Experience had confirmed his previously expressed opinion of the value of this method. The cases fit for this operation are not common, perhaps only one out of

five or six are proper subjects. He recommends primary division of the tendo-Achillis, then, of the posterior tibial tendon, and if this will not bring the foot into good position, open incision of the plantar structures will give a successful result.

THE TREATMENT OF HAIR-MARKS BY ELECTROLYSIS

was advocated by Dr. GEO. H. FOX, of New York, it having been suggested by the successful application of the method for the removal of superfluous hairs. The treatment of superficial nævi by this means was contrasted with scarification, as recommended by Balmanno Squire, of London, and preference given to the electrolysis. The objections are tediousness of operation and severe pain; it is not applicable, on this account, to young children. Some slight scarring must be expected.

Dr. SHERWELL, of Brooklyn, preferred multiple puncture, with needles dipped in caustics, to the electrolysis.

Dr. H. KNAPP, of New York, had obtained good results from extirpation, either by dissection or caustic, and he finds that subsequently the remainder will obliterate. If possible, we should discern the starting-point of the telangiectasis and remove it.

Dr. SHERMAN, of Ogdensburg, reported a case cured by the procedure recommended by Dr. Knapp.

Dr. A. VANDERVEER reported an attempted

SUBCUTANEOUS SECTION OF THE NECK OF THE FEMUR,

in a case of ankylosis of the hip, and explained the method of performing the operation. The lady had suffered with prolonged hip-disease, and being given up as hopeless by her physicians, the limb was allowed to assume a very awkward position, in which ankylosis finally occurred. A subcutaneous operation was attempted, but the saw breaking in the wound, it was found necessary to enlarge the incision and remove the saw with the forceps, virtually making an open wound. After section of the neck of the femur and extension, it was found that tenotomy of the adductors was needed. The limb was now placed in a good position. An abscess occurred at the site of the wound, but the patient finally recovered, and a false joint was obtained. The limb is now straight and useful, with good motion at the hip.

THE DIVISION OF OPTIC AND CILIARY NERVES FOR SYMPATHETIC OPHTHALMIA

was advocated, by Dr. H. D. NOYES, of New York. Two forms of sympathetic ophthalmia are observed: (1) the irritative, (2) the inflammatory. The former sometimes merges into the latter, but the inflammatory form may arise without being preceded by inflammation. Sympathetic ophthalmia of the irritative form, and the milder cases of the inflammatory form, are generally checked by enucleation of the offending eye; in some other cases of inflammation this, for some unexplained reason, is not sufficient. The modification of the original operation of cutting the nerve is performed by going between the internal rectus and the superior or the inferior, into the depth of the orbit, dividing the optic nerve, and everting the globe, in order to completely divide all the nerve-fibres. Some operators divide one or both of the lateral recti-muscles. Simple neurotomy sometimes is followed by reunion of the nerves, the sensibility of the cornea returning in about twelve months; neurectomy, removing a small piece of the optic nerve, is, therefore, to be preferred to simple division of the nerve, with a view to the ultimate success of the operation.

Optico-ciliary neurectomy is to be preferred as a prophylactic in cases where the affected eye is (1) extremely tender on pressure, and (2) subject to repeated attacks of inflammation. Under these circumstances, it will affect the other eye sooner or later. It may also be performed in other cases where enucleation should be performed, but where consent to extirpation of an offending eye cannot be obtained.

In cases of absolute and painful glaucoma this operation has the advantage of reducing the tension of the globe and retaining its normal appearance and size.

Dr. KNAPP approved of all that had been said in regard to the importance of preventing sympathetic ophthalmia, but could not endorse his remark that optico-ciliary neurotomy is in general favor among specialists. He had performed it himself nine times, in one of which gangrene of the globe occurred. Von Gräfe had written a monograph upon the subject and pointed out many cases in which this operation is entirely inadmissible. At the Ophthalmological Section of the International Medical Congress the subject was freely discussed and many bad results and some fatal cases reported. In many cases the operation only serves to delay enucleation until it is too late to be of service.

Dr. ROOSA opposed the operation, and would never perform it.

Dr. L. D. HALLOWELL, of Buffalo, advocated division of the ciliary nerves in proper cases as a preliminary measure, though not intended to be applicable to foreign bodies in the eye.

MEMOIR OF THE LATE DR. JAMES P. WHITE,

of Buffalo, by Dr. AUSTIN FLINT, was presented and referred to the Committee of Publication.

Dr. L. D. BULKLEY, of New York, read a paper entitled,

THE MALIGNITY OF SYPHILIS,

with an analysis of 450 cases, protesting against the views recently enunciated that syphilis may be regarded as a benign disease. Dwelling upon the prevalence of the disease and its varied manifestations, he concluded that it is, in point of frequency, only second to phthisis. It is closely related to scrofula and similar degenerative disorders.

His consideration of the subject was summed up as follows:

1. Syphilis is a constitutional infectious disease of which the first outward manifestation is the chancre, initial lesion, or initial sclerosis at the site of entrance of the virus.

2. While this primary lesion commonly presents points by which it may be recognized, in other instances it is very difficult to speak with positiveness from the local lesion alone, and, therefore, cases presenting only local signs must, as a rule, be excluded from any consideration of syphilis as regards the pathological tendencies of the disease.

3. In a certain proportion of cases constitutional syphilis is a mild affection, even as other infectious diseases occur, with varying severity under different conditions.

4. The causes of the differences observed in certain cases of syphilis are as yet unknown. Individual constitution, surrounding circumstances, the discharge of the virus received, proper treatment, and possibly partial protection through hereditary influence of the disease, are elements of importance in every case.

5. No definite prognosis can be made from the character of the initial lesion of syphilis, as to the progress of the disease if left untreated. Cases which at the beginning seemed insignificant, have in later years proved most serious, while, in many instances of late lesions of syphilis, no satisfactory history at all can be obtained in regard to the initial sore, it having been so slight, or so concealed, as to have escaped notice.

6. In view of the very severe and extensive manner in which syphilis may at some time during its course affect any or all of the tissues of the body, and the destructive pathological tendencies of the disease under-

favoring conditions, syphilis cannot properly be spoken of as a benign disease, although certain cases may, under suitable circumstances, run a very mild course.

SECOND DAY.—EVENING SESSION.

Dr. ABRAHAM JACOBI, President of the Society, delivered the

ANNIVERSARY ADDRESS,

taking for his subject "Infant Feeding, and Infant Foods," after which the Society sat down to its Annual Dinner at the Delavan House.

THURSDAY, FEB. 9.—THIRD DAY—FINAL SESSION.

After prayer, the Society proceeded to the consideration of

MISCELLANEOUS BUSINESS.

Communications were received from County Societies.

The resolution from the Otsego County Society, to relieve certain permanent members from paying dues, on recommendation of County Societies, was referred to the Committee on By-Laws.

The special Committee on the President's Address (Drs. E. M. Moore, S. O. Vanderpoel, Wm. C. Wey, and J. P. Gray) offered resolutions favoring erection of special hospitals for contagious diseases of children. Also, that the conferring of the title of Doctor of Medicine should be by medical colleges only, after the examination and recommendation of an independent Board of Examiners, which Board shall be common to all the colleges.

The Publication Committee was authorized to publish the Transactions at their discretion.

The Committee to act in conjunction with the Society to Prevent Cruelty to Children was continued, and Dr. C. R. Agnew was added in place of the late Dr. Jas. P. White.

Dr. AUSTIN FLINT offered the following resolution:

Whereas, Efforts have recently been made in this country to excite in the minds of ignorant people a prejudice against vaccination,

Resolved, That this matter be referred to the Committee on Experimental Medicine, and that this Committee be empowered to take such measures as may seem to its members requisite for the protection of the public health.

Adopted, and Dr. Flint was added to the Committee.

Dr. JOHN P. GRAY, of Utica, moved, that in view of the important relations of the medical profession to the administration of justice, the time has arrived when the faculty should declare its opinion upon the proper functions and limits of medical-expert testimony, therefore,

Resolved, That the true function of the medical expert is to expound and interpret the results of the pathological conditions, and that in the absence of disease he is not justified in drawing conclusions as to civil responsibility from moral manifestations of conduct, that department belonging exclusively to law.

Unanimously adopted.

By resolution, Dr. Gray was requested to prepare a paper on this subject for the next meeting.

The following papers were read by title:

On Inflammation of the Shoulder-joint, Resulting from Hemiplegia, by Dr. L. E. FELTON, of St. Lawrence County.

Report of a Case of Molluscum Fibrosum, by GEORGE G. HOPKINS, M.D., of Brooklyn.

The Early Diagnosis of Pott's Disease, by V. P. GIBNEY, M.D., of New York.

The Significance of Pain Referred to the Ear, by Dr. D. B. ST. JOHN ROOSA, of New York (see page 152).

Cases of Glaucoma, in which Iridectomy on one Eye seemed to Precipitate an Attack of Acute Glaucoma in the Fellow Eye, by Dr. D. WEBSTER, of New York.

A Few Original Thoughts on Cholera, by H. RAYMOND ROGERS, M.D., of Dunkirk.

And *Facial Paralysis occurring in Connection with Aural Disease*, by S. SEXTON, M.D., of New York.

Dr. D. H. GOODWILLIE, of New York, read a paper on *Application by Insufflation of Medicated Powders to the Upper Air-Passages, for the Relief of Catarrhal Conditions*, which was referred to the Publication Committee.

Dr. E. H. M. SELL, of New York, read a paper

ON THE USE OF AVENA SATIVA,

in which he recommended the use of concentrated tincture of avena sativa or maltine, as a nerve stimulant and general tonic in the neuroses. The concentrated tincture is invaluable as an antidote to the opium habit, and he reported several striking cases which were cured by it.

Dr. SQUIBB offered a resolution that writers of papers for the future sessions of the Society, either limit their papers to twenty minutes, or prepare an abstract for reading, and that any motion to extend the prescribed time shall not be in order. Adopted.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK offered a communication pointing out defects in the medical law of 1880, and asking that appropriate amendments, or a new bill be recommended to the Legislature, so as to define clearly what is meant by a practitioner of medicine, and second, to prescribe a penalty for perjury in registration; as the present law is inoperative against magnetic physicians. These points were embraced in resolutions, which were adopted.

Drafts of bills from the Committee on Legislation were approved and recommitted.

THE REPORT OF THE COMMITTEE ON NOMINATIONS, as follows, was presented and adopted:

President.—Harvey Jewett, M.D., of Canandaigua.

Vice-President.—E. D. Ferguson, M.D., of Troy.

Secretary.—Wm. Manlius Smith, M.D., of Syracuse.

Treasurer.—Charles H. Porter, M.D., of Albany.

Chairman of Committee of Arrangements.—S. B. Ward, M.D., of Albany.

Honorary Members.—Drs. Roberts Bartholow, of Philadelphia; Sidney Ringer, of London; Charles M. Ewing, of New York.

Eligible for Honorary Membership.—Drs. Theodore G. Wormley and William Goodell, of Philadelphia.

After a short farewell address by the President and the usual vote of thanks, the Society adjourned to meet at Albany, on the first Tuesday in February, 1883.

CORRESPONDENCE.

MEMPHIS—ITS SEWERS AND ITS HEALTH.

To the Editor of the MEDICAL NEWS:

A statement has been going the rounds of the newspapers, that the mortality of Memphis has increased since the introduction of the Waring System of Sewerage. This statement would seem to imply that the sewers have, to say the least, been a factor in the increased death-rate.

It may be said that a problem is being worked out here, in which our community especially, and sanitarians generally, are deeply concerned, and as this question is one of public interest, I propose to state, briefly, the facts as far as I am acquainted with them.

This system of sewerage was inaugurated by the laying of pipe, January 20, 1880. House connections were begun March 1, 1880. On July 1, of the same year, twenty miles of sewer had been laid. The system was practically completed, July 1, 1881, when thirty-four miles of sewer-pipe had been laid, and 3579 water-closets had been connected with it.

It will appear from these data, that during the year 1880, the sewers were in operation to a limited extent, and only during the latter part of the year; while they were in full operation during most of the year 1881.

It is proposed to compare the mortality for 1881 with that of 1880. No allusion is made to 1879 and 1878, because they were epidemic years.

The total mortality for 1880 was 1054; for 1881 it was 1276. This increase of mortality was distributed quite evenly through the year. During the last quarter of 1881 the mortality was a little less than for 1880, being 272 against 279 for the same quarter of the year previous.

The increased mortality for 1881 was observed in both the white and the colored races, except for the last quarter of 1881, when the death-rate among the whites was less, and among the blacks was greater than for the corresponding quarter of 1880.

The deaths from zymotic diseases generally were 274 for 1880, and 320 for 1881.

The mortality from all the forms of malarial fevers, including typho-malarial, was nearly the same for each year, being 101 for 1880, and 99 for 1881.

The number of deaths from typhoid fever was 17 for each year. Dysentery destroyed 70 lives in 1881; only 45 in 1880. Diphtheria, 43 in 1881; only 12 in 1880. Consumption carried off 168 in 1881, and 157 in 1880. Acute diseases of the respiratory organs destroyed 102 in 1880, and 124 in 1881.

It is generally conceded that the operation of the sewers has been eminently satisfactory. There is no ground for the complaint of sewer-gas in dwellings, and the pipes are believed to be comparatively free from it.

To July 1, 1881, it had been found necessary to cleanse a portion of the mains, of deposits, only twice; and the laterals not at all. To the same date, only twenty-one cases of obstruction by sticks, rags, etc., had occurred in the six-inch pipes, and these had been removed at an average cost of $15 each.

The only defect in the works yet discovered, has arisen from an error of calculation. It is, that the two fifteen-inch mains, running parallel to the bayou, are too small to carry off readily the sewage from the laterals. As a temporary means of relief to these mains, there have been established at five points overflows into the bayou.

I cannot see how the system of sewers can in any way be held responsible for the increased mortality of 1881. By this system we have been relieved of the great evil of soil-pollution; but it would seem that something else than sewers is necessary to make the health of this city what it should be. What this is remains to be discovered.

It must be remembered that one feature of the Waring system is soil-drainage. This it accomplishes but to a very limited extent, because here the network of pipes encloses no areas less than three hundred feet square, and in many portions of the city, much larger areas are dependent upon these pipes for drainage. Furthermore, the drain-pipes, which lie alongside the sewer-pipes, are, in very many places, twelve feet and more below the surface; and, as the soil contains much clay and is very retentive of moisture, these drains exert no influence in the way of drying the surface soil.

My belief is, though I have been able to obtain no mathematical data, that the general level of the subsoil water has not been materially lowered by the sewer system here; and, in the light of past observations upon this point, in other localities, *we may not reasonably look for much reduction in our death-rate until our drainage is radically improved.*

The water-supply of this city is objectionable upon two grounds:

1. It requires filtering to make it suitable for cooking, washing, or drinking, and this is impracticable for the largest portion of the population.

2. The source from which the water is obtained is open to contamination, through the influence of back-water at certain times, from the drainage of slaughter-houses, stockyards, and sewers.

The investigations of Major Benyard (United States Engineer Corps), made for several months past, and still being carried on, show that when the Mississippi is high, and Wolf River low, a current sets in below the mouth of the present outlet of the city sewers, and carries the water from this locality, as well as that which is polluted by the outflow from Bloody Bayou and Bayou Gayoso, above the point at which the city supply is taken.

The influence of such water as this upon the public health, must, of necessity, be prejudicial. The water company who have recently come into possession of the works, seem determined to remove all objectionable features, and I have no doubt will ultimately give the city good water.

Memphis has an honest and intelligent government, and an energetic and faithful Health Board, who are doing everything in their power to make the city what it ought to be, from a sanitary as well as a commercial standpoint. But Rome was not built in a day!

To Dr. G. B. Thornton, President of the Board of Health, I am indebted for free access to all the records of his office, and for much information pertaining to this subject.

Yours, respectfully,
R. B. MAURY, M.D.

MEMPHIS, TENN., January 24, 1882.

NEWS ITEMS.

ALBANY.

(*From our Special Correspondent.*)

MEETING OF NEW YORK STATE MEDICAL SOCIETY.—In spite of the snow blockade that has interrupted travel to some extent throughout the State, the annual meeting of the Medical Society of the State of New York was held at Albany, convening on Tuesday, the 7th inst., according to appointment, and a large and unusually active meeting was held. New York City was well represented by the President of the Society, Dr. Abraham Jacobi, and by Drs. Vanderpoel, Agnew, Elsberg, Bulkley, Piffard, Roosa, Squibb, Seguin, Gibney, Bull, Sturgis, Rockwell, and others, while from the State perhaps a larger number were present than at any previous meeting. Drs. Moore and Ely, of Rochester; Potter and Roe, of Elmira; W. Manlius Smith, Felton, and many other prominent members of the profession in the State were also noticed to take an active part in the proceedings.

The interest of the session, apart from the scientific work, centred especially around two proposed measures, involving the general and political interests of the practitioner. The first was a new code of ethics; the second, new legislation regulating the right to practise. The first had been referred to a committee at the last meeting, whose report was now presented, and by direction of the Business Committee and the vote of the Society it was made the special order for discussion upon Tuesday evening. The question was one which deeply interested the members, inasmuch as it warranted consultations with irregulars. While the New York City delegation were almost entirely in favor of such a radical change, the State members were opposed to it. A motion offered by Dr. Roosa, of New York, as a substitute for the report, nearly succeeded in passing, although in effect it entirely threw overboard all codes of ethics, and left the subject to each individual prac-

titioner to decide for himself. It was only prevented from being adopted by the decision of the President, that being in effect an amendment to the By-laws, it required a two-thirds vote. There were thirty-nine votes in favor of it, and thirty-seven against it.

This motion is especially noticeable, as it received the endorsement of a majority of the members voting. It is also significant as showing the attitude of the profession in New York to the Code of Ethics of the American Medical Association.

The report of the Committee on Ethics, which was finally adopted, not only amends the Constitution of the Society, but clearly dissolves the connection of the New York State Medical Society with the American Medical Association. The attention of the members was called to this fact, but by a two-thirds vote the measure was carried; a step which will probably again cause discussion when the delegates from the Society present their credentials next June, at St. Paul, at the meeting of the National Association.

The proposed legislation called for by the communication from the New York County Medical Society, contemplated not only compulsory registration, but also the divorcing of the diploma and the license to practise, confining the right to grant the latter to a State Examining Board. It was intended to pass this at this meeting, in order to allow it to receive the endorsement of the Society at once, and to push it through at the present session of the Legislature. The act is expected to become a law within twenty days after its passage. The principles of this bill are set forth substantially in a communication from Dr. Sturgis, whose conclusions are given in another column. Whether due solely to the knowledge that these important measures were coming up for discussion or not, the fact remains that the present is one of the largest and most successful gatherings of the profession of this State that has ever been held.

The papers read were numerous, and, necessarily, brief; quite a number of them were abruptly cut off by the twenty-minute rule adopted on the first day, on recommendation of the Business Committee. The programmes for each session were only to be obtained at the commencement of the exercises, two programmes being issued daily. This method is decidedly inferior to the old plan of providing a complete programme on the first day, which gave the members in advance an idea of the time when papers interesting to them would be presented. The plan adopted is almost equivalent to neglecting to provide any programme at all.

The address of Dr. Jacobi, at the Capitol, on the evening of the second day, was on the subject of the various infant foods now offered by dealers, and the defects and inefficiency of most of them were pointedly considered and condemned.

The report of the Nominating Committee gives general satisfaction.

WASHINGTON.

(*From our Special Correspondent.*)

SMALL-POX IN THE DISTRICT OF COLUMBIA.—While small-pox has been so rife over nearly the whole country during the past winter, this District has been singularly favored. Only one death occurred from the disease during the year 1881, and that was in December. Since that time six cases have been developed, all from the first case, so that Washington is to be credited, up to this date, with only seven cases in all.

Nevertheless, vaccination and revaccination have been vigorously practised, both by the health authorities, by the physicians to the poor, and by private physicians. One of the regulations of the public schools is, that all children must produce certificates of vaccination before they can be admitted.

The National Board of Health have recently issued a circular letter to the heads of Government departments, recommending "that prompt measures be taken for securing, as far as may be practicable, the vaccination or revaccination of all the employés of the Government," and the Secretaries of the Treasury and Interior, and the Postmaster-General have already called the attention of their employés to the necessity of complying with this recommendation.

It is quite a relief to the people of the District of Columbia to feel that they have something to boast of in exemption from small-pox, after the serious misrepresentations that have gone abroad on the subject of "Washington malaria."

SMALL-POX.—The mortality returns for the week ending February 4, give the following number of deaths from small-pox: New York, 20; Philadelphia, 12; Boston, 1; Allegheny, 17; Erie, 1; Montclair, N. J., 1; Richmond, 12; Norfolk, 1; Dayton, 10; East Liverpool, O., 1; Indianapolis, 1; Louisville, 1; Chattanooga, 1; Milwaukee, 4.

For the week ending January 28, there were 9 deaths in Hudson County, N. J., 1 in San Francisco, 4 in New Orleans, and 1 in Holyoke, Mass.

On the 6th inst. there were 14 new cases and 6 deaths, and on the 7th, 6 cases and 2 deaths, from the disease in Chicago; and during last week 18 new cases in Richmond.

HEALTH IN MICHIGAN.—For the week ending January 28, 1882, the reports indicate that bronchitis and influenza have increased, and that tonsilitis, membranous croup, typho-malarial fever, remittent fever, and diphtheria have considerable decreased, in area of prevalence.

Cases of small-pox are reported as follows: in Crystal Lake township, Benzie Co., January 7; in Prairie Ronde, Kalamazoo Co., January 24; in Port Huron township, January 24; in Watson township, Allegan Co. (1 case), January 26; in Pontiac township (4 cases derived from a tramp), January 28; at the villages of Menominee (2 cases), Waucodah (3 cases), and Spalding (3 cases), in Menominee Co., January 28; at Bay City (convalescents), January 28; at Escanaba, Delta Co., January 28; at Detroit, January 28; at Grand Rapids (convalescents), January 31; and in Park township (brought from Leesburg), St. Joseph Co., February 2, 1882.

LEPROSY IN MINNEAPOLIS.—We are informed that a leper, aged twenty-six, died at Minneapolis, on February 1. The disease first manifested itself upon his arrival in this country, six years ago, and during this time he has endured great suffering.

VACCINATION OF EMPLOYÉS, ETC.—The Louisville and Nashville and Short Line Railroad Companies have followed the example of the Pennsylvania Company, in requiring a certificate of vaccination from its employés. The contagion of this exemplary act we hope may outrun the small-pox.

In a letter to the Postmaster-General, the President of the National Board of Health strongly recommends the vaccination or revaccination of all persons employed in the Government departments.

An ordinance has been published by the City Councils of Richmond, Va., compelling the vaccination of all persons who have not been vaccinated within twelve months, except in cases where any regularly licensed physician shall declare it to be injurious or

unnecessary. Any person refusing to be vaccinated, or to allow his or her child, children, or wards to be vaccinated within fifteen days after the passage of this ordinance, is liable to a fine of five dollars.

OBLIGATORY VACCINATION IN SWITZERLAND.—During the passage of a new law on epidemics, the Swiss National Council (*Gaz. Hebd.*, January 1), adopted by ninety votes against twenty-three the principle of obligatory vaccination. Every infant born in Switzerland must, according to this law, be vaccinated during the first year of its life, or at latest during its second year; and infants born out of Switzerland, if not previously vaccinated, must submit to the same rule. No child can be permitted to frequent a public or private school without a certificate of vaccination.—*Med. Times and Gaz.*, Jan. 14, 1882.

DISINFECTION OF CLINICAL THERMOMETERS.—In a letter to the *Lancet*, January 14, 1882, Dr. HASSALL draws attention to the importance of thoroughly disinfecting clinical thermometers after use, by washing them in a solution of permanganate of potash or carbolic acid, so as to avoid any danger of transferring contagious diseases from one patient to another.

ADULTERATION OF FOOD AND DRUGS BILL.—A bill has just been presented in Congress to prevent the adulteration of food and drugs. According to its provisions an article is adulterated:

a. In the case of drugs:

First. If, when sold under or by a name recognized in the United States Pharmacopœia, it differs from the standard of strength, quality, or purity laid down therein.

Second. If, when sold under or by a name not recognized in the United States Pharmacopœia, but which is found in some other pharmacopœia, or other standard work on materia medica, it differs materially from the standard of strength, quality, or purity laid down in such work.

Third. If its strength or purity fall below the professed standard under which it is sold.

b. In the case of food or drink:

First. If any substance or substances has or have been mixed with it so as to reduce or lower or injuriously affect its quality or strength.

Second. If any inferior or cheaper substance or substances have been substituted wholly or in part for the article.

Third. If any valuable constituent of the article has been wholly or in part abstracted.

Fourth. If it be an imitation of, or be sold under the name of another article.

Fifth. If it consist wholly or in part of a diseased, or decomposed, or putrid, or rotten animal or vegetable substance, whether manufactured or not, or, in the case of milk, if it is the produce of a diseased animal.

Sixth. If it be colored or coated, or polished or powdered, whereby damage is concealed, or it is made to appear better than it really is, or of greater value.

Seventh. If it contain any added poisonous ingredient, or any ingredient which may render such article injurious to the health of a person consuming it: *Provided*, That the National Board of Health may, with the approval of the Secretary of the Treasury, from time to time declare certain articles or preparations to be exempt from the provisions of this act; *and provided further*, That the provisions of this act shall not apply to mixtures or compounds recognized as ordinary articles of food, provided that the same are not injurious to health, and that the articles are distinctly labelled as a mixture, stating the components of the mixture.

Section 5 further provides, "That, in order to carry into effect the provisions of this act, the Secretary of the Treasury is hereby authorized to appoint, from names submitted to him for that purpose by the National Board of Health, one or more suitably qualified persons as special inspectors, and as public analysts for adulterated food and drugs at such ports of entry as the Secretary of the Treasury may deem expedient; and it shall be the duty of the National Board of Health to prepare instructions governing the work of such inspectors and analysts, which, when approved by the Secretary of the Treasury, shall govern their action, and that of collectors of customs, in preventing importation from foreign countries of food or drugs adulterated within the meaning of this act."

THE RED CROSS SOCIETY.—The International Committee of the Red Cross Society of Geneva has decided to offer for public competition three prizes of 2000 francs each, with second prizes to the amount of 500 francs. The subjects of the three essays are: 1. On Improvising the means of Treatment of Wounded and Sick. 2. On Improvising the means of Transport. 3. On Improvising an Ambulance or Field Hospital. The object sought is to obtain by the union of the three a complete work on the art of improvising the means of assistance for wounded and sick. The committee is desirous of grouping methodically all available information as to the measures by which the three important branches of treatment, transport, and ambulance may be best extemporized in cases where special provision has not been made beforehand for them. Details are given of the various matters grouped under these three headings in the circular issued by the committee, to which we must refer those interested in the subject. The essays may be in French, German, or English. They must reach the President of the International Committee, Rue de l'Athénée, 8, Geneva, Switzerland, before April 1, 1883; each essay must bear a motto, and be accompanied by a sealed note containing the name of the author. The committee reserve the right of withholding any of the prizes, should the essays appear to the jury appointed to examine them not to possess sufficient merit. The jury will be composed of members of different nationalities. If prizes are awarded, the essays are to be the property of the Society, under the condition of being published by it within a year from the date of the award of the jury.—*Lancet*, Dec. 31, 1881.

HOW TO AID INJURED PERSONS.—Gen. McClellan has accepted the chairmanship of the committee recently formed in New York, whose purpose is to teach persons of all classes how to give first aid to the sick and injured, pending the arrival of a physician or surgeon, and to give instruction in nursing and in the laws of health. A large number of physicians have already volunteered their services in giving the needed instruction, and eighteen classes have been formed. Similar work has been in successful operation in London for nearly five years, under the auspices of the Society of St. John, of Jerusalem. The importance of this, the newest phase of New York's philanthropy, in supplying such instruction to the police, firemen, railway employés, workmen in factories, and, in fact, to all classes, must be generally appreciated and approved by the public and medical profession. We trust to hear soon of other cities following New York's example.

REMOVAL OF THE ENTIRE UTERUS.—On January 3, Sir WILLIAM MACCORMAC removed the entire uterus, on account of epithelial cancer of the cervix, in a woman, aged thirty-four, who had been admitted into St. Thomas's Hospital, under Dr. Ord's care, with serious intestinal obstruction. An incision was first made

through the abdominal parietes from the umbilicus to the pubes. It was then found that the cavity of the pelvis was completely filled by a tense, thick-walled cyst, which flattened the rectum against the sacrum, and was the cause of previous severe obstruction. The uterus and its appendages were at first completely concealed by the tumor; and until it was evacuated, no room could be obtained to perform the necessary manipulations. The cyst, which afterwards proved to be ovarian, contained very offensive pus, and it was impossible to prevent partial escape of its contents into the peritoneal cavity. On the cyst being partially emptied, it was separated from the almost universal adhesions it had contracted, and removed along with the uterus. On the completion of the operation, the large double-barrelled T-shaped drainage-tube recommended by Bardenheuer was inserted, and the two ends projecting from the vagina were utilized for frequent irrigation. No attempt was made to suture the pelvic outlet. The abdominal wound was closed in the usual manner. On the fifth day, there was evidence of some suppuration opposite the lower part of the wound, which was therefore reopened. Some pus escaped, and the cavity was washed out. The temperature, which had risen to 102.6°, fell soon afterwards; and the patient is now (ten days after the operation) making rapid progress towards recovery. Eucalyptol was the antiseptic agent employed for irrigating, as well as for the spray and external antiseptic dressings.—*British Med. Journ.*, Jan. 14, 1882.

PURITY OF ICE.—The New York papers have lately been agitating the question of conveyance of disease by ice. The *World* recently interviewed Dr. S. O. Vanderpoel, formerly Health Officer of New York, who, in reply to the inquiries propounded by its reporter, said: "I have no doubt that disease can be disseminated just as well by ice as by water. If I am not mistaken, some time ago certain ice formed from pond water near Boston was suspected to have caused sickness, and when the ice was examined it was found to contain numbers of impurities. I do not believe that freezing forces out foreign substances, and the assertion that disease-germs are expelled cannot be sustained, because these germs cannot be isolated so as to be examined microscopically. I think a distinction should be drawn between miasma and malaria. The first properly belongs to animal germs, and the other to vegetable. Now these animal germs are effectually destroyed by oxidization when exposed to the air, and is the reason why in rivers or in large lakes where no sewage enters the water the ice from it may be used with impunity."

THE JOURNAL OF NERVOUS AND MENTAL DISEASES.—Messrs. G. P. Putnam's Sons writes to us, requesting us to state that the report that this journal has been "sold out" or discontinued, which has obtained currency in some periodicals, is without foundation.

SHALL WOMEN PRACTISE MEDICINE?—Mrs. Mary Putnam Jacobi, in an article in the *North American Review*, ably discusses this subject, and declares that "the profession of medicine must be chosen deliberately, and not at hap-hazard, from a strong and genuine taste, and not from the mere pressure of economic necessity; it must be seriously prepared for in youth; must be entered upon at the age at which at present many women marry; may not yield its best returns until full maturity has been reached; must be adopted, therefore, if at all, for a lifetime. Hence is required either an accidental celibacy or a deliberate renunciation of marriage for the sake of medicine, such as is not dreamed of in regard to any other work; or else such an adjustment of domestic claims as shall render them and the practice of medicine by married women mutually compatible."

A SPANISH HOSPITAL IN PARIS.—The *Siglo Medico*, of Madrid, states that steps will shortly be taken to open a hospital in Paris, for the relief of necessitous Spaniards. The Spanish colony in that city already exceeds thirty thousand, many of whom are in indigent circumstances, and dependent entirely, in case of sickness, on public benevolence. The new hospital will owe its inception mainly to Duke Fernan-Nuñez, the Spanish ambassador, and will be modelled, as far as possible, on the plan of the French Hospital at Madrid.—*British Med. Journ.*, Jan. 14, 1882.

A GENEROUS GIFT.—Dr. G. S. B. Hempstead, a member of the Scioto County (O.) Medical Society, has donated his large library to the Society.

PERSONAL.—The London *Graphic*, of January 21, contains an excellent likeness of the late Dr. John W. Draper, New York.

BEQUEST TO DARTMOUTH MEDICAL COLLEGE.—Mr. Edwin W. Stoughton by his will, which was admitted to probate on the 1st inst., gives $2000 to Dartmouth Medical College, for its Pathological Museum.

DIED.—On January 8, 1882, JOHN FLINT SOUTH, F.R.C.S., in the eighty-fifth year of his age. Mr. South is best known as the translator of Chelius' *System of Surgery*, to which he added numerous valuable original notes.

It was largely through the energy of Mr. South, that the remains of John Hunter were interred in Westminster Abbey, the epitaph being from his pen.

NOTES AND QUERIES.

A COMMON MISTAKE OF DRUGGISTS.

A CORRESPONDENT writes us that again and again he has sent patients to drug-stores to obtain "India-rubber tissue," or "pure thin sheet rubber," for covering poultices and such like uses; and nearly always he finds them sending "gutta-percha tissue" or India-rubber cloth. "The former tears easily, curls up and becomes useless at the temperature of a properly made poultice, and is unsuitable for medical purposes; the latter being made partly of cloth, absorbs discharges and quickly becomes foul. Apparently our friends of the pill and the pestle do not know what 'India-rubber tissue,' or 'bandage rubber,' as we believe it is technically known to the trade, really is."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 31, TO FEBRUARY 6, 1882.

SUMMERS, J. E., *Lieutenant-Colonel and Surgeon.*—Medical Director Department of the Platte. Leave of absence further extended one month.—*S. O. 20, C. S., A. G. O.*

WOODWARD, JOSEPH J., *Major and Surgeon.*—Granted leave of absence for six months on Surgeon's certificate of disability, with permission to go beyond sea.—*S. O. 23, A. G. O., January 30, 1882.*

WOODHULL, A. A., *Major and Surgeon.*—The leave of absence granted him in S. O. 227, A. G. O., 1881, is extended one month and ten days.—*S. O. 27, A. G. O., February 3, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

INFANT FEEDING AND INFANT FOODS.

THE ANNIVERSARY ADDRESS,

Delivered before the New York State Medical Society, February 8, 1882.

BY ABRAHAM JACOBI, M.D.,
PRESIDENT OF THE SOCIETY.

MR. VICE-PRESIDENT, LADIES AND GENTLEMEN, MEMBERS AND DELEGATES OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK: I hold in my hand a report of the Committee appointed to co-operate with the New York Society for the Prevention of Cruelty to Children, "in all things pertaining to the physical and moral safety of infants and children." The report I refer to was read in last year's meeting, and has been widely distributed by the above-named Society. One of the measures contemplated and advised in it was, that there should be a place or places in large cities, where the infants and young children of the poor might be supplied, at cost, with the simple though sufficient articles of food. These simple and sufficient articles of food were milk, barley, oat-meal, and, for those no longer infants proper, eggs. Their value as infant food for those who were without breast-milk, was taken for granted, and considered almost in the light of an axiom. To make it so has been one of the duties of my life. Truth, however, is frequently suspected because of its very simplicity, and often do we see complicated and roundabout means and measures resorted to in preference to plain and direct ones. Now, what I have to say may, in part, appear very common-place and trifling, because of its application to common-place things and interests. But questions are involved which it has taken, and will still take, much time and labor to solve. To render the results hitherto obtained available, the normal feeding of the infants possible, and to protect them from the injuries inflicted by ill-directed love, ignorance, and the evil-devised plans and frauds of what is called commerce and industry, will be the object of the brief remarks which I shall have the honor to make before you in regard to the dangers to which our infants are constantly exposed.

Mortality amongst infants is very great. In Europe, out of one hundred born alive, eighteen die before they reach the end of their first year. Out of one hundred who die at all ages and of all diseases, in New York City, twenty-eight are less than a year old. The causes of these deaths vary; it is a characteristic fact, however, that of all those taking place in infants under a year, from 40 to 53 per cent. are the results of diseases of the organs of digestion.

Thus the attention of the physician called to see a sick child is mostly claimed by the alimentary canal. His care and that of the mother or attendant is therefore due to preventive measures mostly. The best preventive measure, and sometimes it proves curative, is the breast-milk of mother or wetnurse. That is an axiom, an undisputable law of nature, as long as the circumstances of the case are favorable. In view of the great mortality in the first two months, breast-milk is the one and indispensible food for those under two months. A mother who refuses to nurse *at least that time* for other than reasons of health or life, is an accomplice in causing, perhaps even the only cause of, the death of her offspring. It is true that a baby may be taken sick with intestinal disease in spite of being nursed at the breast, for there are *many* causes of disease; it may, however, occur that babies are taken sick *because* of being at the breast. And it is those cases that both mothers and physicians ought to be well acquainted with. Sometimes it is not the breast-milk which is at fault, in the beginning, but the faulty use it is put to. Many babies suffer intensely because they are not limited to intervals of from 2 to 4 or 5 hours, as required by either age or constitution. In their cases, by too frequent feeding, both the milk of the mother and the digestion of the infant, are impaired. Here regularity is the sole indication. Sometimes, though fortunately in few cases only, there appears to exist an idiosyncrasy not explained, on the part of the baby who cannot thrive on the milk of the mother, and may do so after a change of food. In many cases, however, there are demonstrable dangers in the very breast-milk of either mother or nurse; there may by an undue percentage of fat, or of cheese, or of salts, or of sugar, or even accidental admixtures. These may occur in the secreting organ (thus blood may be found in the milk) or be traceable to the circulating blood of the whole system; of the latter they may be the very constituents, or foreign bodies floating in it. They can be classed as either morbid dispositions or as actual admixtures. Women suffering from constitutional syphilis, chronic consumption, or anæmia, extensive rachitis, severe nervous derangement, hysterical or other, those suffering from care and hard work, and those who are compelled to take a great deal of medicine, will serve their babies best by not nursing them at all.

In regard to the influence of the medicines, the opinions *have* been divided. It was claimed that milk being a secretion of the gland, and not a transudation from the blood, would not contain foreign material to any great extent. That is true so far as an absolutely healthy woman and normal milk are concerned. But the first period of lactation yields colostrum, not normal milk, and very often the latter is changing into a colostral condition, such as it was soon after birth, containing different-shaped fat globules, more sugar, soluble albumen, in fact, real blood serum. This may take place in every case of impaired health. And the more serum of blood is contained in any milk, the easier is the admixture of soluble substances circulating in the blood. Such substances are ethereal oils, coloring matter, iron, iodide of potassium, arsenic, zinc, mercury, salines, bismuth, lead, antimony, nitrate of potassa, magnesia, all of which have been frequently found in the milk, and frequently missed. They will be missed the more frequently the healthier the woman and its mammary secretion. But, as I formulated the subject some years ago, milk secreted from an insufficient mamma, by a woman not in full health and vigor, by an old woman, by a very young woman, by an anæmic woman, by a convalescent woman, who has consumed a large portion of her albumen, be it circulating or tissue albumen, by a neurotic woman with frequent disturbances of the circulation—milk, in fact, which is not the normal transformation of the elements of the mammary glands, but consists of more or less transuded serum, is apt to be impregnated with elements circulating in the blood. The indications on one hand for the permission to nurse, on the other, for the administration of medicines to a nursing woman, require, therefore, a

greater strictness than is usually conceded. At all events, the good results obtained in many cases of ailment on the part of the infant, *by artificial feeding, in preference to nursing*, are better than accidental.

Those infants who are thus deprived of breast-milk, or never had it, or have an insufficient supply of it, require artificial feeding. The material resorted to ought to be as much like mother's milk as possible; and naturally, when human milk cannot be had, animal milks are selected. Amongst them only two are available to any extent, that of the goat and of the cow. If there be any objection to either, it is principally valid in regard to the former. For the chemical incongruities and other difficulties, to which I shall briefly allude in regard to cow's milk, are even more pronounced in the case of goat's milk.

My remarks of this evening I expect to be of a practical nature throughout, and brief. Thus I shall not try to go into chemical or physiological questions beyond the time allotted or the opportunity afforded. Therefore, I shall allude to but two points which it is interesting to appreciate, in order to understand why it is that cow's milk, as a sufficient substitute for mother's milk, must necessarily be a failure.

Human milk and cow's milk differ mainly in that the percentages, and probably also the properties, of fat and of caseine contained in them, differ widely. The percentage of fat in cow's milk is larger than in human milk, and, on close observation, we shall learn that woman's milk contains as much fat as the young digestive organ can tolerate. From what we know of the diastatic power of the infant pancreatic gland, we must conclude that its property of digesting fat is but slimly developed soon after birth; and daily observation proves that such is the case. When you examine chemically the normal alvine digestions of the infant, well mixed, uniform, and yellow, you will discover not only fat acids, but free fat to the extent of about 12 per cent. Some more fat leaves the intestines in a saponified condition. Many of the passages which have been believed to contain caseine in excess, because of their white color, were found to contain large quantities of fat. And all this happens when the normal infant is fed exclusively on normal breast-milk. Now if much fat is not required nor absorbed under normal circumstances, if fat acids form so easily when the digestion is apparently normal, with the constant tendency of deranging digestion; if we know, as we do, that even normal breast-milk contains more fat than the infant has any use for, we must admit that in artificial feeding, with cow's milk or other material, we are in greater danger from giving too much fat than too little. Good milk has been called that which contains most fat, say from four to five per cent. The more cow's milk deserves the title of being good—that is, fat—the greater is the danger arising from giving it to infants without considerable modification. This result authors appear to gradually appreciate. When Forster fed a baby of four months with cow's milk and rice decoction in the proportion of 1 to 4, all the albuminous substances and sugar of this mixture had disappeared when the fæces came to be examined. Thus they were entirely digested, but of the ashes 34, and of the fat 30 to 40 per cent. were found unchanged. This experiment proves, in the opinion of Prof. Bollinger, whom I rejoice in quoting, that a milk less rich in fat is more adapted to serve as infant food than one with a large percentage of fat; and further, that cows whose milk is destined to be used as infant food, ought to be fed so as to reduce rather than increase the amount of fat contained in it. A good authority, Prof. Feser, makes the distinct statement that the milk he examined on the Alps of Switzerland, and which he prefers greatly as children's food, contained less fat than that from the cows in the neighborhood of a large city. If that be so, and it is so, I recommend as a matter of practice that the morning milk, with its lesser percentage of fat (butter), should be given, in preference to evening milk, if any at all.

Now, if the excess of fat be one of the causes why cow's milk should not be employed as infant food, why not remove it or diminish its percentage? Easily said, not easily done; for when milk is allowed to stand, and the cream to rise, the milk at the same time changes its reaction. Instead of being alkaline or neutral, it becomes acid, and acid milk is a danger which an infant must be protected from. Some years ago, Lefeldt and Delaval invented each an apparatus which, by rapid centrifugal motion, separates the cream from the milk very thoroughly. Such an apparatus may, perhaps, be found useful in reducing the normal fat of cow's milk to an acceptable standard in the future. For the present, however, I know of no proceeding which accomplishes the end in view; and, while submitting to the unavoidable, I must protest against the avoidable occurrence which is reported to have taken place in a court of justice but lately. In one of the skim-milk police cases—and unfortunately there are less "cases" than adulterations—the expert for the defence, a well-known chemist, tried to clear his client by proving him a public benefactor, inasmuch as Dr. Jacobi objected to an excess of butter in the milk used for children.

Caseine is represented in cow's milk in a larger percentage than in human milk. To reduce its relative quantity, compared with the rest of the solid constituents, is possible by the increase of these only. There is no method by which its absolute quantity in a given amount of milk could be diminished, except such as would render the remaining part of the milk unfit for use. This diminution, moreover, would have to be a very thorough one, for a mixture containing more than 1 per cent. of caseine has been found to be indigestible by Hammarsten, and by Biedert. But these are not the only objections to cow's-milk caseine. Not only is its percentage in the milk too great; its chemical and physical properties *differ greatly* from that contained in human milk. Mineral, acetic, and tartaric acids, epsom salts, phosphate of lime, form a dense and hard coagulation with the caseine of cow's milk, while human milk coagulates in loose and small flakes only, under the same circumstances. Cow's milk, when introduced into the infant stomach, forms hard curds; if the organ be strong, or the infant liable to vomit easily, as most of them are, thick massive pieces of cheese are thrown up, and relief will follow. If no vomiting occur, these hard masses are propelled into the intestinal tract, where sometimes they give rise to obstruction. Sometimes, however, they irritate the canal to such an extent, that *diarrhœa* is the result. In both cases lumpy cheese is the main constituent of the evacuations. In every case of infant diarrhœa, the examination of the passages ought to be made; in many cases the appearances will be found as described, and no case of the kind will terminate favorably unless the food be changed. To say that these cases will occur, would not do justice to the facts. They are very frequent, I have seen hundreds; but lately a child of sixteen months of age, and of six pounds in weight, was presented to me with the same symptoms, and with the additional remark, not only that everything had been done by the medical adviser to stop the exhausting diarrhœa, but also that a cow had been purchased for the sole purpose of furnishing pure milk for the suffering baby. That suffering baby was instantly improved when the pure milk was stopped, and more suitable food was substituted.

The objections to cow's milk, as the exclusive diet of infants, in place of mother's milk, which cannot be had, are dependent on its very chemical composition and physical properties. These cannot be changed by

the most studious and successful attempts at procuring the most uniform and pure article possible. That, however, does not prove that a bad or indifferent milk is as good and useful as the very best milk from the very best cows. The inference is rather this, That the employment of inferior milk is criminal when good milk can be had through precaution, care, and industry. To have accomplished that purpose is the pride of several European cities. In some it was through medical societies that the idea was started and put into effect, to procure as good milk as cows of good stock, well fed under favorable sanitary conditions, could furnish. Stuttgart had the first establishment of the kind; that in Frankfort-on-the-Main commenced its operations in 1877, with thirty cows, and increased that number to eighty-one in 1881. The amount of milk produced, and delivered to consumers, in 1881, was 313,563 litres (quarts), more than ten quarts per cow daily. The establishment is private property, but to earn the support of the public, and to secure the desired co-operation of the physicians of the town, the proprietor bound himself not to engage in any other business, and solicited the control and advice of a committee, consisting of three delegates of the medical society, one veterinary surgeon, and one chemist. Great pains are taken in the purchase of animals of a good stock, all of them thus far being imported from Switzerland. Before they are admitted, they are examined by the veterinary surgeon, who superintends the institution, and keeps a regular record of those who may fall sick. Two months before calving the milk is not sold at all. The age of the cows of from three to eight years is considered the only available one. The stables are well ventilated, and washed, drained, and connected with the system of city sewers. The floors of the stalls, the ceilings, and the lower part of the walls are cemented. The skin of the animals is looked after with great care. The stables are so near the city limits, that the milk cannot suffer by transportation. It is tightly corked in half-quart and quart glass bottles (this process being cautiously watched), and speedily delivered. Printed directions for its further treatment accompany the article. Besides, stress is laid on avoiding a prejudice on the part of the public, to which I have raised objection long ago with but very partial success, viz., not to select the milk of a special cow for the special use of the same individual, but to mix and equally distribute the milk of the whole dairy.

A great innovation for practical purposes, based on good experiments and long experience, is that no change of food takes place, and poisonous, purgative, or otherwise injurious admixtures to the food of the animals are avoided. Dry food only is given, viz., 15 kilog. (30 pounds) of hay, 6½ kilog. (13 pounds) of meal and bran, 6 grammes (1½ drachms) of salt, and spring-water to drink.[1]

Human knowledge and foresight have almost exhausted themselves in these praiseworthy efforts. But the result of them all is *good cow's milk, and no equivalent for mother's milk.* But do I mean to say that cow's milk, given pure, or cow's milk mixed with water, is absolutely injurious, poisonous, to babies? Far from it. The undeniable fact that there are infants who thrive on that exclusive diet, or whose general condition of health remains such that no medical or medicinal interference in their behalf appears called for, would give the lie to such an exaggerated opinion. Still, there are a great many infants *who appear* to thrive better than *they actually do.* Many grow fat and rotund on improper food, no immediate harm makes its appearance, and still you see many such as increase in weight, even more than the average infant, and still lay the gradual foundation to future ailing. For such fatness and rotundity means, too frequently, rachitis, and requires watching and change of food. Still, the number of infants remaining in good condition on that food is not very small. What does it prove? Nothing else but that the digestive processes permit of a certain latitude, that nature does not do routine work, and that the sum total of vital processes do not respond to certain occurrences, or influences, like reagents in a chemical test, where the same process always yields the same results. There is *no food on which certain infants will not thrive.* But when, in a large percentage of cases, the same unfortunate results are exhibited, and when these can be traced to their exact and uniform cause, that particular food is to be condemned. The assertion of many that cow's milk is an exact substitute for human milk, is the counterpart of that which claimed equality for animal and human blood. The practice, based upon this assumption, resulting, as it did, in the transfusion of animal blood into the human circulation, outlived itself very speedily.

Cow's milk, as a universal substitute for mother's milk, has lost its credit with many through the differences in the article; which, however, as long as no adulterations are perpetrated, are less marked than the same secretion of the human being. If that were not so, how does it happen that all over the civilized world substitutes are sought for, offered, and purchased, though milk be as cheap and handy as anything else? Why is it that to avoid cow's milk, untold risks are run in procuring more expensive, more unknown, and more unreliable vegetable compositions, which seldom keep the promises loudly displayed on the labels? What are these promises? What does it mean when they claim to take the place of mother's milk?

Mother's milk is considered the best prepared article of food known, though, as you have been told before, it may be—it could have been improved upon. Perhaps *it is* the best, though; at least there was a time when we all were of that opinion; for perhaps the surplus of fat, which passes off undigested, may serve some purpose hitherto unknown. An ideal article of food must serve two purposes and consist of two classes of constituents. It must, in the infant, supply the growing tissue with material sufficient to take the place of that which is constantly wasted, and to allow a surplus for increase; and, secondly, supply fuel for the purpose of keeping up the production of an equable temperature and the functions of the organs, mainly those of respiration. The first requirement is fulfilled by the proteinous, or albuminous, substances, the other by carbo-hydrates. This statement would require modifications, if it were the object to be absolutely correct, for the two classes will supply each other, act vicariously for each other, even change into each other, under certain circumstances, in the complex machinery of the human system. The albuminous tissue-builder in the milk is mainly caseine, sometimes, also, albumen; the second class is principally represented by fat and sugar. In vegetables the first class is represented in the gluten, the second mainly in the starch. If you add, that in the milk, the ideal food, the proportion of the first class to the second is about 1 to 4, the vegetable substitutes are to be judged, in regard to their mere chemical composition, to that formula of about 1 to 4.

But it is not the chemical formula alone which determines the rank of a substance as a nutriment. To the equivalents of the chemical formula of cow caseine infant mathematics would not object, did not the infant stomach revolt against it. Thus it is not exclusively the chemistry of an article, but its digestibility, which comes into question. Now, not everything is equally digestible for everybody, sick or well, old or young,

[1] Dr. V. Cnyrim, in "Frankfort-on-the-Main, Its Hygienic Conditions and Institutions." Ed. by Dr. A. Spiess, 1881.

adult or child, child or infant, infant or newly born. And particularly is that so with regard to starch, which forms such an overwhelming part in the composition of vegetables, and particularly of those which are mainly used for the purpose of the manufacture of infants' foods.

Starch is changed into sugar and rendered digestible by the secretion of two sets of glands, the salivary glands and the pancreas. The latter does not possess that function before the end of the first month of life. The former begins to perform the same function, to a certain degree, immediately after birth. The experiment has been made by Schiffer, Korowin, and many others. Starch, enclosed in a small bag, is introduced into the mouth of the infant. After a certain time the starch is found to be transformed into sugar. To collect fifteen grains of saliva in a baby of two or three weeks took from fifteen to thirty minutes; in a baby of two months, but one or two minutes. Thus two facts result from these experimental observations: 1. That starch is digestible at any age; 2. That the transformable and digestible amount of starch is but very small in the first weeks of an infant, and increases gradually. About the eleventh month the digestive property of the saliva is equal to that of an adult, when the quantities are equal.

The inferences to be drawn are: 1. That farinaceous foods may contain starch, but *starch must not be the main part* of the food; 2. That when they contain a great deal of starch it is best to change it, by a thorough baking process, into dextrine, which is changeable into sugar, and is easily absorbed and utilized; 3. That those farinacea ought to be selected for infant food in which the proportion of gluten to starch favors the former.

There is another consideration of vast importance, which, when the infant foods now in the markets were first manufactured, could not be known. Starch is not the same article everywhere. In different substances it requires different times to be transformed into sugar. Potato starch requires 2 to 4 hours, that of peas 1¾ to 2 hours, wheat ½ to 1 hour, barley 10 to 15 minutes, oats 5 to 7 minutes, rye 3 to 6 minutes, maize 2 to 3 minutes.

Guided by these facts, I invite you to scan with me a number of farinaceous substitutes—their claims, promises, and powers. You will notice, there is not one of the men or companies who supply them but is loud in the praise of his gift to infancy; not one but ranks in his actual or alleged estimation as the arch-benefactor of mankind.

Justus von Liebig's (the great chemist) substitute consisted of the flour of wheat and barley malt, bicarbonate of potassium, water, and milk in certain proportions. For about twenty years this preparation has been the subject of eulogies and reproaches, until in its original form it has been nearly given up; for its home preparation is not so easy as its inventor claimed.

It requires too much care and attention from a person of intellectual undersize. Besides, everything containing sugar is liable to decompose in summer by fermentation and moulding; all preparations *really dry* have a bad taste. Moreover, the phosphate of lime, which, it is true, is found in sufficient quantity in both wheat and malt, does not get into the solution, and finally, *for its preparation*, you always require *milk*, milk in winter and summer, milk in city and country, with all its actual or alleged dangers. Still more, it has, though prepared ever so carefully, proven unsuccessful in too many cases. Diarrhœa has often resulted from its use. Numerous attempts have been made to put it up for the market in such a shape that little time and no intellect might be required for its final use. *Loefflund's* article has the merit of being no fraud as far as I know; that of *Liebe* I paid attention to when it was first largely advertised for sale. A dozen bottles contained in a box were examined; their consistency and composition differed considerably. Another preparation, alleged to be compounded according to the prescription of the great chemist, is sold with the name of his son, *Herman von Liebig* attached to the recommendation of the label. He has a great deal *too much* to say in its praise. "1. This remarkable preparation accomplishes everything that can be expected of a substitute. 2. Although the flour is a perfect nutriment in itself, I still recommend on my labels its mixture with cow's milk. 3. Where good cow's milk cannot be had, condensed milk may take its place. 4. Infants fed on cow's or condensed milk, ought to have it mixed with my flour." You see the unsophisticated public must come to the conclusion that the object and destination of this food is no other but to be purchased.

Next in order is *Nestle*, as widely known as plantation bitters and cider vinegar. This food consists of milk, wheat flour (alleged to be baked, for the purpose of crushing the cellulose and cell membranes), sugar, and salts. As a chemical critic says (H. Mueller, in *Pharm. Centralhalle*, xvi., 1875, n. 34), he publishes no analysis but advertisements only; and he knew how to advertise. I remember well when the people of New York awoke one morning to find their libraries increased by a big pamphlet containing the new revelation. It was written by no less a person than an emeritus university professor of pathology, in his time a justly celebrated man, Lebert, who passed his very old age in the neighborhood of where Nestle had established his health, life, and money-breeding factory. Every such pamphlet commences with a declaration of principles. This begins by telling the reader that cow's milk is more "nourishing" than human milk; that, however, the addition of water does not make it any more similar to the latter; and that the nursling ought to have cow's milk at once alongside that of his mother—probably to improve upon nature's plan. Then why does he want or recommend substitutes, if cow's milk does so well? even better than well? For the simple reason that if people would feed their own cow's milk, they would not purchase Nestle's; and in order to induce them to do the latter, he tells you that your cows may be tubercular, may be fed improperly, their milk may be adulterated with water, or may contain disease germs. Nestle's cows are not tubercular, we have to infer, are not fed improperly, their milk cannot be adulterated, nor does it contain disease germs—indeed not. For it is the milk of *Swiss cows*, with such a halo round their horns, that even that public-spirited institution, called St. John's Guild, of New York, publishes an advertisement of Anglo-Swiss food, on the last page of its pronunciamento on the bringing up and feeding of little children, which is distributed gratuitously, or for an annual contribution of three dollars.

We are assured that Nestle examines his materials very carefully, uses bread only made of the very best wheat, and the crust only; and that the starch is transformed into dextrine and sugar, under a pressure of a hundred atmospheres, by overheated steam. Thus Nestle's food is not only the very best nutriment for infants, but also for mothers who would fain raise a supply of milk in their own breasts, though it appears that that would be an uncalled-for desire in the face of all that is said about Nestle's food being a perfect substitute. All of which is respectfully submitted by Mr. Nestle's prompter, Prof. Lebert, or, perhaps, rather by Prof. Lebert's prompter, and most of which is untrue.

Many years ago, fifteen or more, when Nestle and Lebert discharged their pamphlets, advertisements, and agents upon America, I was induced to try and employ Nestle's food; I could not say that in children

of a few months or a year it did any harm; on the contrary, it was fairly tolerated by most of them. I consented even to add my name to those of others recommending the article—the only time I ever did so in my life. A few years after, another advertisement appeared which advised rather against the purchase of the former preparations and recommended the recent modification. It was then, at last, that I resolved to scrutinize what I had recommended in good faith without any examination. I found, 1, that the contents of a number of boxes did not closely resemble each other; 2, that the main substance was made up of starch; 3, that even the cell membranes were not equally crushed, and a great many not changed at all. It has also been found, and urged mainly by Eliza McDonogh (*Inaug. Diss.*, Zurich, 1877), that the fragments of the microscopic elements exhibit the appearance of mechanical destruction, and not that brought about by heat. J. Miescher also states that he finds no essential difference between Nestle and common flour. Iodine yields instantly its blue reaction; the starch elements are partly free, partly still locked up in their cells. Some particles are albuminous, they turn yellow with iodine. In his experiments the watery extract was alkaline, in those of McDonogh it was acid, and contained but little dextrine. Cnyrim found in the boxes examined by him, sugar and dextrine to the amount of 45.56 per cent., but still 20.76 per cent. of starch were left without any change whatsoever. And the result of Jacobsen's examinations is that the contents of the boxes are not alike.

Gerber, also a large advertiser, and Nestle's Swiss rival in America, claims to have improved Nestle's flour by a difference in the process of preparation; the methods of which, however, are not communicated. His flour is wheat, which is again praised as the one article containing all the material required by the growing body in the smallest possible bulk. The same enumeration of the elements is made of an organic salt, and their mixture with organic substances is spoken of as if it were a new discovery. Potassium and phosphatic combinations, albuminates, carbon hydrates, fats, are whirled about in the most impressive and bewildering manner by every one who has a cheap article for sale at a high price. The greatest stress is always laid on the presence in the article offered for sale of all the chemical elements necessary for the building-up of the body. But that presence alone, I repeat, is not sufficient; chemical figures and equivalents still enjoy too much respect and a sort of superstitious veneration. A *thorough preparation preliminary to digestion* is required, though the proportion of elements in a mixture were ever so appropriate. In regard to wheat, however, *this proportion is not the very best* at all, for wheat contains more starch than do barley or oat-meal.

In regard to both of them, Nestle and Gerber, Drs. Altherr and Lorch, in a little book entitled "On the Weighing of Infants for the purpose of determining the Nutritive Value of Woman's Milk, Cow's Milk, Nestle's and Gerber's Flours, and Liebig's Soup," Erlangen, 1877, have no great praise to bestow. Both are declared to be improper foods for the newly born and infants in the first few months; but they admit in the later months of life, when farinaceous foods of all kinds are well tolerated, they also may be given in the same manner. Similar observations have been made in the Child's Hospital, at Berne, Switzerland; and similar remarks are due to the *Anglo-Swiss Food*, which contains milk, some gluten, and plenty of starch, like the others.

In all of the twenty-two European infant foods examined by Eliza McDonogh, the starch was never changed to such a degree as to render the recognition of its source impossible. Wheat, corn, rye, barley, could always be recognized under the microscope. A number of the granules were broken up it is true, but many more were intact. Thus, not even the very exact and uniform distribution of the starch is accomplished. All of them consist of baked flour of some kind, either by itself or mixed with sugar, milk, or salts. There are some, however—for instance, that of Hartenstein—consisting of wheat and oats, which has not even undergone the baking process.

Part of these European preparations have been naturalized with us. Some have made a great reputation, and probably money for many beneficent manufacturers, agents, and salesmen. But they are not alone in the field. Saul slew a thousand, David ten thousand. Europe has twenty odd infants' foods, America more than twice that number. Infants must no longer complain of lack of interest roused in their behalf.

Nature is the same all over; the nature of all natural things alike; that of wheat, oats, and manufacturer, wherever they be found. Thus the same results in regard to the composition of "infant foods" are reached here as in Europe. But a few days ago I was pleasantly surprised by the brief statements of Dr. E. Cutter, who, for *Gaillard's Medical Journal* (Jan., 1882), has undertaken the task of studying (microscopically) all the infant foods in our market. His researches, naturally, refer mainly to the proportion of gluten to starch. And some of his statements I shall refer to here, desiring to give them the greatest possible publicity. I wish the brief article of his would be distributed in a hundred thousand copies, reprinted in every secular paper, read from every platform and pulpit of the land. For it is time that fraud should be stopped, and a nefarious trade suppressed.

Amongst the better preparations are *Mellin's Food*. It claims to be the only substitute for mother's milk, and not farinaceous. It is not the only substitute, but the starch is converted into dextrine, as in *Horlick's Food*.

Franklin Mills Wheat Flour contains more gluten than most of the rest. So does *Arlington Wheat Meal*, which is ground coarsely, and contains much gluten. Also *Hawley's Liebig's Food*, which contains wheat gluten cells, barley gluten cells, barley tegument, wheat starch, and cooked granular masses, which do not polarize light.

Mead's Mulled Wheat Flour, a coarse flour or meal, which does not polarize light well; a good preparation.

Baby Sop is made of unhulled oats, malted and crushed, and contains all its elements; gluten cells of characteristic shape, and starch grains smaller than those of wheat.

As you descend the ladder, there is *Keasbey & Mattison's Infant's Food*. No gluten cells; consists of grape sugar and dextrine, and claims to contain alkaline phosphates.

Mother's Breast-milk Substitute is better than its ignorant advertisements; it contains gluten cells, bundles of wheat starch, barley starch, and gluten granules.

Imperial granum, the salvator for invalids and the aged, an incomparable aliment for the growth and protection of infants and children, a superior nutriment in continued fevers, and a reliable remedial agent in all diseases of the stomach and intestines; that which makes strong bone and muscle; that which makes good flesh and blood; that which is easy of digestion, never constipating; that which is kind and friendly to the brain; and that which acts as a preventive of those intestinal disorders incidental to childhood—Imperial granum food, which claims that the starch, impurities, and soluble matter are effectually excluded, and that the gluten only is retained, *shows no gluten cells under the microscope*, and is no better than it should be, no better than common flour, which, when fine and white,

is deprived of three-fourths of its gluten, and no better than *Savory & Moore's Food*, which is also like common flour. (E. Cutter.)

Ridge's Food is advertised as "a perfect food for infants." Ephraim Cutter tells you how perfect a food it is. It contains the beard of wheat, wheat starch mass, starch bundles apparently of maize, caked mass of starch which does not polarize light, starch grains, starch granules, and small gluten granules. And he adds: "The proprietors must add gluten cells, at least in the proportion found in wheat or maize, to bring the product up to the standard of wheat flour."

Crosby's Brain and Nerve Food, which claims to be composed of vitalized phosphates from ox-brain and wheat-germ, consists almost exclusively of starch. There are no characteristic gluten cells, no nerve-fibre, no axis cylinder fibre, no ganglion, nor multipolar cell. The advertisement claims that the brain is that of the ox, but the label states that the brain is that of the fish. Label advertises 730 parts of starch in 1000, claims some gluten; if this exists, it is the granular gluten of common flour. There are 270 parts of so-called vitalized salts asserted to be in this food; that is, salts in connection with the organic substances named. If this *be so, all the albumenoids in all the foods* in the market are vitalized, also. There is but little gluten, if any, in this food. (E. Cutter.)

Blanchard's Glutena, 90 per cent. of starch, 10 of gluten, the reverse, exactly, of the claim made for the food.

Blair's Wheat-food, abundance of starch, no gluten.

Redmond's Cerealine, starch, very little gluten.

Durkee's Glutena, wheat, almost exclusively starch.

Farwell's Gluten Flour is advertised as "gluten left behind after the starch is blown out," contains starch, almost no gluten.

Victor's Baby Food is *said* to "resemble mother's milk closely," and *is* like cracker and biscuit ground up.

Taylor Brothers' Pure Bermuda Arrow-Root consists of *potato starch*, with an occasional addition of arrow-root.

Hubbell's Prepared Wheat, almost exclusively of starch.

No gluten is contained in *New York Food Company's* cold blast flour, barley flour, buckwheat flour, India wheat flour, Lost Nation wheat flour, Common Minnesota flour, Hazleton flour, Puritan flour, Patapsco flour, Underwood flour, fine granulated wheat flour.

Gluten Flour, New York Health Food Company, is common flour. The most superficial examination exhibits starch in abundance.

After all this, with all my heart I assent to E. S. Gaillard's editorial remarks, which are as follows:

"It is almost criminal that such great questions, affecting the health, and, therefore, the happiness and wealth of a nation, should be left to the ignorance of the miller and the baker; to the foolish customs of society, to the equally foolish test of the mere appearance of bread, and to the fashionable restaurants and hotels. Manufacturers of foods for the sick, and, above all, for infants, should be held to the strictest accountability. It is the highest duty of the physician to learn the facts in regard to meal foods, and to use his information for the benefit not only of the sick, but of the whole community." And experience shows, that as the committee report referred to expressed it last year, the community insists, with the utmost pertinacity, upon giving their babies, as soon as weaning time arrives, or before, such articles of food as they know nothing about. When an adult sits down to a meal and finds placed before him articles of food with which he is not familiar, he makes inquiries in regard to such articles before eating them. The baby, however, is credulously fed upon things with which the child, father, mother, or doctor has not the least familiarity; all of these foods which are sold in large quantities have a composition which is unknown to the public. When a manufacturer deigns to say anything about his merchandise, it is to the effect that the food offered is the best in the market, that it is the proper thing and only thing for children and invalids of all ages, that the relation of the albuminous substances to carbo-hydrates is exactly correct, and that a package costs a certain amount of money. In regard to this subject the public appear to be smitten with absolute blindness. They insist upon forgetting that the man who offers for sale, and advertises at a very heavy expense, does so, as society is constituted, for his pecuniary advantage solely. To say that when the article offered is not good it will find no market, is deceiving yourselves, experimenting on your baby, relying on the character of a single man or corporation, on the honesty or intelligence of the manufacturer's chemist, or his superintendent, or his workmen, on the nature and condition of the elements used in the composition of the article, and on ever so many influences, which can work before the manufactured article gets into the hands of the consumer. Why the sellers and advertisers of unknown compounds should be more trusted than those who raise and sell a simple article of food, such as milk, which is constantly adulterated, can hardly be perceived. Is it necessary to say that the factory furnace is lighted more in the interest of the proprietor than for the benefit of the public?

Still, in regard to the growing evil, which has assumed vast proportions, the profession is at fault, to a certain extent. There are but few but are aware of the inexpediency and sometimes danger attending the exclusive feeding of cow's milk, and look for substitutes. Examples of infants thriving on almost any food are numerous; the public taste runs in the direction of the unknown; thus the responsibility of advice or assent is but a slight one; many of the foods in the market come in a pleasant form and convenient for use; thus the food-business firm certainly thrives. Professional men have become used to look upon the sale of patented foods as something quite unobjectionable. Those imbued with the strictest sense of ethics, who would not patent an invention, nor tolerate the fellowship of a professional man who so does, who frown upon patented medicines, because they are unknown and unknowable compounds, who object to reducing medical science to a mercenary standpoint, these very men forget their habits and principles when the question of patent-right and secrecy comes up in regard to patent foods. If I add, that many of the scientific journals of Europe, particularly those in Germany, dedicated to the study of children's diseases, are frequently used for the purpose of discussing the merits and effects of some new infant foods, it is only to show to what extent the evil has grown.

No profound thinking is required to appreciate the fact that a great many of the articles offered for sale are unmitigated frauds; and that a few are available compositions. But the very fact that they are compositions, that everything organic may spoil, that every compound depends on too many circumstances which are apt to interfere with its uniform condition, and that when you rely on a compound, you rely at the same time on a proprietor, his foreman, his workman, his chemist, you feel that you are easily deceived or disappointed. Besides, for an article, the constituents of which you can purchase at a low price, you are taxed to an inordinate extent.

And why all this? Because cow's milk is found to be defective, when compared with mother's milk. These defects I have pointed out. It contains too much fat, and too much caseine, the latter of abnormal condition. Instead, however, of correcting the faults of milk,

the latter is simply superseded and exchanged for something else. Is potato starch or even wheat, more similar to mother's milk, than is that of the cow? Now the proportions of fat and caseine can be regulated by the addition of water; but dilution is not the only function of the water added to the milk; the digestibility of the latter is also increased.

When albuminous material is subjected to artificial digestion with pepsin, and the process ceases, it recommences when more water is added. When the amount of water in the mixture is large, digestion will take place in a lower temperature than without it. Many digestive disorders in the living are due to lack of water, particularly in infants, who seldom or never are supplied with it in addition to what they obtain in their regular food. Infants who are apt to perspire much, either well or rachitic, who are kept in warm beds most of the time, who are exposed to summer heat, and lose much moisture through their skin, ought to be offered water a great many times in the course of the day. Particularly fat infants, who are mostly developing a rachitic or scrofulous disposition, ought to drink plenty of water. It accelerates tissue changes, and, therefore, animals which are to be fattened are habitually deprived of water. The rule then holds good in infant alimentation, that food, whatever it be, shall be given in considerable dilution.

But in the face of all the advantages water has, it is by itself not the proper dilution for the *caseine of cow's* milk. Some admixture must be found which is apt to overcome the dense coagulations of caseine referred to before. The particles of caseine must not be permitted to remain in close juxtaposition, but separated from each other to such an extent that coagulation in the stomach will take place in small loose flakes of the kind presented by curdling mother's milk. This object is accomplished by all farinaceous substances, without regard to their large or small percentage of starch; also by gum arabic, and gelatine. Of the farinaceous substances, I have but two to recommend, barley and oat-meal. And for good reasons. The starch they contain is more easily dissolved and transformed by saliva than that found in wheat, which is the stock in trade of the infant-food manufacturers. And, moreover, there is less of it in them than in wheat.

The barley and oat-meal are the two substances I mostly employ, as their chemical constituents are nearly alike, with the exception of a large portion of fat in oat-meal, which is not found in barley. Barley water, or thinned and sweetened oat-meal gruel, may be given to the child even at the breast. The indications for the use of one or the other lie in the condition of the infant. Where there is a decided tendency to constipation, I prefer oat-meal; where there is no such tendency, as usual, or perhaps even a tendency of the bowels to be loose, I employ barley. The "prepared" barley is a good preparation for older children only, for the whiter it is the larger is its percentage of starch. It is safest, as no mistake or deception can then take place, for every mother to grind the whole barley in a common coffee-grinder of her own. The younger the baby the more advisable does it become to boil the whole barley for hours, to secure the contents of the bran. A teaspoonful of either is boiled in from five to eight ounces of water, with some salt, for twelve or fifteen minutes, the decoction to be quite thin for very young infants, thicker for later months, and then strained through a linen cloth. Infants of four or six months are to have equal parts of this decoction (which ought to be made fresh for every meal), and of boiled cow's milk; some sugar besides. At an early age, the thin decoction, at a later, the milk ought to prevail in the mixture, which ought to be given at a temperature of 80–90°. The newly-born, which has to wait some days for his spring to open for him, is best fed with a mixture of from four to (in summer) six parts of thin barley water, and one part of boiled milk. A baby of two months will take the same mixture in the proportion of from two or three to one.

I beg leave to quote a single author. Biedert, a conscientious worker, the author of competent contributions to medical science, and particularly to infant hygiene, himself the inventor of a cream mixture for the use of well and sick infants, expresses himself in the following manner in the very circular accompanying his preparations: "The first demand on a method of nourishing infants must be this—that the nutriment is tolerated by all infants, including the feeble and sick, in a manner similar to mother's milk. Now I have found that a food coming up to this requirement, must not contain more than 1 per cent of caseine. Accordingly, cow's milk must be diluted with an indifferent thin decoction (oat-meal or barley.) In the beginning, the dilution must be in the proportion of 1 to 3 or 4; this admixture must be gradually reduced. This is the very mixture which surpasses all compounds thus far recommended, and all the artificial preparations." And still in the face of this testimonial, than which I do not wish a more positive one, he invents a cream mixture.

Though my remarks must necessarily draw to an end, I must not close without at least *one additional word* in regard to some other constituent of infant food, Beside sugar, which is required both by taste and physiological necessities, the addition of common table-salt in moderate quantities both to cow's milk and to farinaceous substances is advisable.

The addition of chloride of sodium to the food is the more important the more the milk is mixed with a vegetable decoction. Carnivorous animals crave no salt; herbivorous, however, a great deal, although in their food the *absolute* amount of chlorine and sodium is as large as in that of the former. They are easily drawn by hunters into fields and woods strewn with salt; and the instinct of mankind has early taught how to add more salt to herbaceous than to animal food.

We find that the craving for salt grows in proportion to the amount of potassium salts contained in the food. In that of herbivores there is twice or even four times as much potassa compared with its chloride of sodium as in that of carnivores; potatoes, with their large amount of potassium, combined with chlorine and phosphoric and citric (pomic) acids, necessitate the addition of large quantities of chloride of sodium. In the food of carnivores, however, who eat whole animals, one equivalent of potassium is nearly balanced by one of sodium and one of chlorine.

Potassium salts and soda salts both exist in the blood, the former principally in the blood-corpuscles, the latter entirely in the serum or watery part of the blood. There is chloride of potassium in both corpuscles and serum, but phosphate of potassium in the corpuscles alone. Now if there should ever be in the blood more phosphate of potassium than can be taken up by the corpuscles, it will be immediately decomposed by the chloride of sodium in the serum—chloride of potassium and phosphate of sodium are formed, and these are both rapidly eliminated by the kidneys, and pass away in the urine. By this means, chloride of sodium is carried away, and must be replaced: in other words, vegetable food requires the addition of a great deal of salt.

The substitution of cow's milk for woman's milk necessitates the addition of salt, for a similar reason; for while 1000 parts of human milk contain only 0.70 chloride of potassium, 1000 parts of cow's milk contain 1.30

There may be infants—I have been told of more cases than I have seen myself—who do not bear barley.

Others may not bear oat-meal. If so, or if for some reason or other it is wise or whim to discontinue them, it must not be forgotten that, though feeding a breastless child *without* cow's milk, appears preposterous, feeding with cow's milk *alone* is dangerous. I do not permit it. I want an admixture at all events capable of diluting, as it were, the caseine. For that purpose, and for that alone, I formerly recommended gum arabic or gelatine. However, our knowledge of these substances has since improved. Prof. Uffelmann, in Rostock, had a little patient, otherwise healthy, who carried a gastric fistula. Through a large opening in his abdominal and stomach wall, he experimented on the child's digestion. Unmistakable and numerous observations taught him that both arabic gum and gelatine are not only emollient and soothing, but directly nutritious. Thus the list of those substances which may be added to boiled cow's milk, to make it available as the regular food for infants, is by no means small. They all come up to the requirements we look for in such substances. They must be perfectly simple and recognizable. They must be accessible, and for sale everywhere. The mode of preparing them must be perfectly simple and easy. They must be cheap.

They must be as nearly the substitute of mother's milk as an imitation can be like the original. They must be alike for throne and den, for Fifth Avenue and Mulberry Street, for the wet-nurses for the throne and for Fifth Avenue come also from the dens and from Mulberry Street. It is not wise to forget that nature is republican in principle and democratic in practice. If too often there be no equality before a court of so-called justice, *there is* equality before that of physiological law.

CARTWRIGHT LECTURES.

ON THE EXPERIMENTAL METHOD IN MEDICAL SCIENCE.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, February 7, 1882.

BY JOHN C. DALTON, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

LECTURE III.

NERVOUS DEGENERATIONS, AND THE THEORY OF SIR CHARLES BELL.

(*Concluded from p. 149.*)

WE will now pass to the second topic for the evening, namely, Sir Charles Bell's Theory of the Nervous System.

Sir Charles Bell's theory of the nervous system is of so recent a date, comparatively speaking, that its traces have not entirely disappeared from our nomenclature. The student will still find among the synonymes in some anatomical text-books such names as the "respiratory nerve of the face," or the "superior and external respiratory nerves of Bell." But the system of which these names formed a part has become so obsolete that their former significance is hardly remembered, and even the distinctive features of the theory itself have been forgotten in the discussion of more important topics connected with the nervous system.

Among the eminent medical men of the present century, perhaps none have attracted more cordial admiration than Sir Charles Bell. His earnest and strictly professional ambition, his restless mental activity, his versatility of talent, and his genial and enthusiastic disposition secured him a rapid success and a position of acknowledged superiority. "Anatomist, surgeon, author, artist, and critic," he taught anatomy by lectures and demonstrations, was the equal of Cooper and Cline in practical surgery, published his magnificent works on the *Operations of Surgery* and the *Anatomy of Expression*, illustrated by himself, and created the reputation of the Middlesex Hospital as a centre of medical instruction. When he received the Order of Knighthood, in 1831, at the same time with Herschel, Babbage, and Brewster, he thought more of his companions than of his title. "The batch," he said, "makes it respectable." He always retained a strong attachment to his early friends and family relatives, and to the pleasures and sports of a country life; and if he experienced some disappointment in regard to the success of his scientific opinions, this was fully compensated by his general popularity and his high professional reputation.

Bell's attention was especially attracted to the nervous system in 1807, a few years after his arrival in London, and while occupied as lecturer in a private medical school, established there by himself. In his demonstrations, he was struck with the apparent complexity of the nervous apparatus, and the difficulty of presenting it fairly to the comprehension of his audience. His mind dwelt persistently on this subject, with a view of reaching some more simple and intelligible arrangement of what seemed confused and disconnected. His thoughts were first directed to the anatomy of the brain, which, he says, at that time "occupied his head almost entirely."[1] He puzzled over the varied form and structure of the cerebrum and cerebellum, the processes, protuberances, and ganglia at the base of the brain, and the connections and course of the different cranial nerves. He tried to reduce these complicated parts to something like order in his mind, and to divine the secret of their anatomical relations.

This was the origin of his new system in cerebral anatomy, and when once it had assumed a distinct form, it grew in importance, and took entire possession of his conviction and imagination. He made it the subject of his lectures, and speaks of it in his correspondence with the greatest enthusiasm. "I hinted to you," he says, in a letter to his brother in Edinburgh, "that I was *burning* or on the eve of a grand discovery." "I really think this new anatomy of the brain will strike more than the discovery of the lymphatics being absorbents." "My object is to lecture it, to make the town ring with it, as it is the only new thing that has appeared in anatomy since the days of Hunter, and, if I make it out, as interesting as the circulation or the doctrine of absorption."[2]

Up to this time there is no trace of any experimental investigations by Bell in regard to this subject. His system was wholly inferential, and based on the visible facts of anatomical structure. But a year or two later he felt the necessity of making some experiments, especially as he had formed the intention of printing his views in a pamphlet for private distribution. He hoped, by this means, to elicit the opinion of the representative men of the profession, and to see whether his innovations would be likely to meet with their approval.

Accordingly, in 1810,[3] he records having made two experiments, with a satisfactory result; so much so that he believes he is now about to establish his system on facts "the most important that have been discovered in the history of the science;" and in 1811, his essay was printed, under the title, *Idea of a new Anatomy of the Brain*, submitted for the observations of his friends, by Charles Bell, F.R.S.E.[4]

---

The idea developed in this essay, and the importance attached to it in the mind of its author, can be best understood from Bell's own account of its origin and growth. In a letter to his brother, a year before, he details his plan of investigation and the object he wished to accomplish. He had already reached the conviction, on anatomical grounds, that the several divisions of the encephalon were different from each other in function, and especially that a wide distinction of this kind existed between the cerebrum and the cerebellum. But how gain access to these deep-seated and vascular parts, so as to experiment upon them? This seemed too difficult an undertaking. It might be possible, however, to expose for that purpose the spinal cord and its nerve roots, and this is what he accordingly did. "It occurred to me," he says, "that as there were four grand divisions of the brain, so were there four grand divisions of the spinal marrow: first, a lateral division, then a division into the back and forepart. Next it occurred to me that all the spinal nerves had within the sheath of the spinal marrow two roots: one from the back part, another from before. Whenever this occurred to me, I thought that I had obtained *a method of inquiry into the functions of the parts of the brain.*"[1]

That is to say, experiments on the anterior columns of the spinal cord, or the anterior nerve roots, would throw light on the functions of the cerebrum, with which they were anatomically connected; experiments on the posterior columns of the cord, or the posterior nerve roots, would indicate the function of the cerebellum, to which, he thought, these parts belonged.

These are the experiments described in the *Idea of a New Anatomy of the Brain*, and this is the meaning attributed to them by its author. He found that irritation applied to the anterior part of the spinal cord produced contraction in the voluntary muscles; while a similar injury, inflicted on its posterior part, did not do so. On laying bare the roots of the spinal nerves, he could cut across the posterior fasciculus without convulsing the muscles; but touching the anterior fasciculus at once produced convulsions. "Such were my reasons," he says, "for concluding that the cerebrum and cerebellum were parts distinct in function, and that every nerve possessing a double function obtained that by having a double root."[2]

The distinction made by Bell between the two divisions of the encephalon is this: The cerebrum is the organ of the mind, of conscious sensation and volition. Consequently, the anterior roots of the spinal nerves, being connected with the cerebrum through the anterior part of the spinal cord, are subservient to both sensation and volition, and when artificially irritated cause contraction in the voluntary muscles. The cerebellum, on the other hand, presides over the secret or unconscious operations of the bodily frame, as in the vital action of the internal organs; consequently, irritation of the posterior columns of the cord, or the posterior nerve roots, has no perceptible effect on the voluntary muscles. A spinal nerve, accordingly, possesses two roots because it performs two sets of functions: one, those of consciousness and volition, derived from the cerebrum; the other, those of unconscious vital influences, derived from the cerebellum. The cranial nerves, however, have for the most part only a single root, and exercise but one set of functions, corresponding to their place of origin. Thus "the eighth nerve (par vagum) is from the back portion of the medulla oblongata, which belongs to the cerebellum; the ninth nerve (sublingual) comes from the front portion, which belongs to the cerebrum. The first is a nerve of the class called *vital* nerves, controlling secretly the operations of the body; the last is the motor nerve of the tongue, and is an instrument of volition."[1] This is the substance of the views contained in the essay of 1811.

Bell was much disappointed in the impression produced by this pamphlet. It turned out an "unpropitious experiment," for it "excited no criticism, and threatened to stifle the enthusiasm of the author." Bell himself says, regretfully, that this announcement from which he expected so much, "failed to draw one encouraging sentence from medical men." But we can hardly blame them very much for this apathy. The systematic ideas of the author, however attractive to himself, might not have the same interest for others; and his experimental proofs were certainly insufficient to command belief on their own merits. Indeed, we now know that they do not really bear the significance which he attached to them. The anterior and posterior nerve roots are not connected respectively with the cerebrum and cerebellum; and we cannot use them in our experiments to determine the separate functions of the brain. It was no doubt a suspicion of this physiological non-sequitur that prevented the profession at large from appreciating the pamphlet as its author had hoped.

But notwithstanding this temporary discouragement, Bell afterwards returned to the subject with new vigor, and soon came to regard his former work as only the introduction to a more extended system. In his first essay, the anatomy of the brain was the main subject of the research, the nerves and their distributions being only secondary; but in his theory as afterwards developed, the nerves and their distributions occupied the prominent place. This matter, in 1814, was already, he says, "ripening in his head," and in his lectures on the nerves for that year he promises to "lay open a fine system." Like his anatomy of the brain, this new system increased in importance the more he thought about it. Year by year he enlarged its proportions and seemed to anticipate from it greater results than ever. He gradually brought it into the form of a series of communications to the Royal Society. In 1819 he regarded it as nearly complete, and fully worth the labor it had cost; containing, as he believed, the materials of a grand system destined to "revolutionize all we know of this part of anatomy, more than the discovery of the circulation of the blood." By the time the first paper was ready for presentation he was abundantly satisfied with it, and declared that he had made "a greater discovery than ever was made by any one man in anatomy."

In this communication[2] Bell presented the main principles of his new arrangement of the nervous system with special reference to the nerves of the face. The paper had been prepared by its author with much care, and he offered it to the Royal Society as the result of several years of thought and investigation.

This time he had no reason to be disappointed, as the essay attracted everywhere attention and approval. In speaking of a reception which he attended soon afterwards "my paper," he says, "has done me as much good as if I had bought a new blue coat and figured French black silk waistcoat. One gentleman called it the first discovery of the age." He received a number of complimentary letters in regard to it, which he says were enough to show that he was "not a visionary" on the subject. "It will hereafter," he adds, "put me beside Harvey."[3]

This paper of 1821 well deserved the praise bestowed upon it; for it contained the announcement of Bell's

most lasting and undisputed discovery, namely, that the facial nerve, or *portio dura* of the seventh pair, was not a nerve of sensibility, but was exclusively a channel for muscular action and the nervous medium of expression in the face. The importance of this discovery, both scientific and practical, was abundantly manifest; and it was sustained by direct and satisfactory experiments on the living animal, as well as by observations on the human subject. It is evident that Bell did not get at the whole truth in regard to this nerve; for he represented its action as limited to the involuntary movements of respiration and expression, and considered the voluntary motions of the face and lips as provided for by the fifth pair. But it is very seldom that all the details of so complex a subject are mastered by one person or at one time; and the primary facts of the motor character of the facial nerve and its insensibility, as contrasted with the extreme sensibility of the fifth pair, were then fully established upon incontestable evidence.

Bell, however, was much more interested in the general plan of his new classification, than in any of its details, which he valued mainly as illustrations or proofs of his system as a whole. He continued to develop this system in a series of papers addressed to the Royal Society; and it was afterwards embodied, with some necessary modifications, in his *Nervous System of the Human Body*, published in 1830.

Bell's conception of the arrangement of the nerves was this: All the nerves of the cerebro-spinal system were divided into two great classes or groups. The first group was that of the *regular*, *original*, or *symmetrical* nerves; namely, the thirty-one pairs of spinal nerves and the fifth pair of cranial nerves. All these nerves arise by two roots, upon one of which is a ganglion; they pass out laterally, to successive divisions of the body; they are all subservient to voluntary motion and common sensibility; they are distributed to every part of the frame, but are symmetrical and simple in their arrangement. The second group was made up of the *irregular* or *superadded* nerves. These do not arise by double roots, and have no ganglia at their origins; they come off from the sides of the medulla oblongata and upper part of the spinal cord, and, instead of being distributed regularly to successive parts of the frame, are sent to remote organs, which they combine in functional activity. They, therefore, have the character of being superadded, for a special purpose, to the original system of regular nerves. They constitute the great group of *respiratory nerves*, which are distributed to a variety of organs, and instead of going out on each side straight to their destination, often pass through the body in a longitudinal or oblique direction. They are:

1. The facial, portio dura of the seventh pair; respiratory nerve of the face.
2. The glosso-pharyngeal nerve; distributed to the tongue and pharynx.
3. The par vagum, or pneumogastric; the nerve of the lungs, heart, and stomach.
4. The spinal accessory, or superior respiratory nerve of the trunk; distributed to the sterno-mastoid and trapezius muscles.
5. The sublingual, or the nerve of articulation.
6. The phrenic, or great internal respiratory nerve.
7. The long thoracic, or external respiratory nerve of the trunk.
8. The fourth nerve, or patheticus; distributed to the superior oblique muscle of the eyeball.

These are the nerves which produce the appearance of irregularity or confusion in the nervous system because they often cross the track of the regular, symmetrical nerves, and are distributed to organs already supplied by them.

This last fact gives the key to the functional peculiarity of the superadded nerves. According to Bell, an organ which performs only a single function has but one nerve supplied to it, and whenever an organ receives nerves from two or more sources, it is because it performs as many different functions. This explains why certain muscles, like the sterno-mastoid and trapezius, already supplied with nerves from the regular or symmetrical system, also receives branches from the respiratory system. The former nerves enable them to perform ordinary the acts of voluntary motion; the latter bring them into occasional involuntary unison with the act of respiration. This is illustrated in a still more striking manner by the two nerves distributed to the face; namely, the fifth pair, supplying the face both with sensation and voluntary motion,[1] and the facial nerve, or seventh, a superadded nerve, which controls the involuntary motions of the face in breathing;[2] or, as he says, "when the muscles of these parts are in associated action with the other organs of respiration."

The respiratory nerves, however, come into play, not only in the motions of respiration proper, but in all acts connected with the entrance and exit of air from the lungs; as, in speaking, singing, coughing, gasping, or sneezing. They are also the agents in all movements of expression, or the emotional affections of the frame. This is especially marked in the seventh pair, which regulates the involuntary changes of expression in the face. But it applies also to the manifestations of emotion in other parts; as, in the hurried respiration of anxiety, the retardation or quickening of the heart, and the sobbing of the diaphragm in grief, excitement, or depression. Under every strong impulse the central organs of respiration are stimulated or disturbed, and thus bring into associated action all their subordinate parts, as organs of expression.

Beside this, the nerves of respiration, wherever they may be, have more vitality than other nerves; for the movements connected with this function will continue to be performed after all manifestations of sensibility and volition have disappeared. Thus these nerves form a great system by themselves, distinguished from the ordinary or regular nerves by their mode of origin, their functions, their distribution, and their vitality.

Evidently, there was much of real value in these observations. They placed in strong relief the fact of associated respiratory motions. The expansion and collapse of the nostrils or lips, accompanying the action of the thorax, are occasional in man, constant in some animals, and always increase in proportion to the intensity of respiration. They are truly respiratory motions, as much so as those of the diaphragm. The sterno-mastoid and trapezius muscles are also brought into action whenever breathing is obstructed or laborious. The classification which Bell constructed on this basis, and illustrated with so much ingenuity, has a certain charm about it, and is plainly marked with the talent and originality of its author. But, even as a system, its joints do not all bear inspection, and it contained from the outset certain defects which become after a time plainly perceptible.

Bell showed by his experiments and observations that the seventh nerve controls the involuntary motions of expression and respiration in the face, and that these motions are abolished by its division or injury. If he had accepted this fact for its own value, and had assumed nothing further, he would have been secure. But he believed, in accordance with his system, that these involuntary movements were *the only* ones under control of the seventh nerve, and that sensibility and volition were provided for by the fifth pair. This idea influenced his mind to such an extent that he was led to conclude,

[1] Philosophical Transactions, 1821, pp. 410, 411, 413, 417; and 1822, p. 284.

[2] Philosophical Transactions, 1821, pp. 406, 410, 414.

after division of the fifth pair alone, that the voluntary movements of the lips were paralyzed, while those of respiration continued.[1] Magendie, on the other hand, who believed in nothing but direct experiment, soon afterwards repeated this operation on the fifth pair, and declared that he could not perceive any paralysis of the lips produced in consequence.[2] We now know that he was right, and that the fifth pair does not animate any of the superficial muscles of the face. If that be true, according to Bell's principles there ought to be *two* other nerves distributed to this part; one for its voluntary, the other for its respiratory functions. But, in fact, it has only the seventh pair, which serves for both.

Bell's classification of the respiratory nerves, with regard to their origin, is by no means perfect in its details. These nerves were said to differ from the others in having no ganglia at their roots, and in originating from a middle tract on the sides of the medulla and spinal cord. But both the pneumogastric and glossopharyngeal nerves have ganglia at their roots, which are as real, though not quite so conspicuous, as the Gasserian ganglion of the fifth pair. Again, the origin of nerve roots, in a nearly continuous line, from the lateral tract of the medulla and spinal cord, is certainly a marked feature in the glossopharyngeal, pneumogastric, and spinal accessory nerves. On the other hand, it cannot be asserted, with any plausibility, of the facial, sublingual, and patheticus.

The last-named nerve was associated with the respiratory system because it was regarded as causing the upward rolling of the eyeball in involuntary movements and emotional expressions. Everything connected with this subject had for Bell a great attraction. His book on the *Anatomy of Expression* was his earliest publication in London, and first called attention to him as a man of ability. He gave lectures on the same topic to professional artists, and the exercise of his talent in painting and modelling was always for him a source of pleasure in connection with his anatomical pursuits. This, probably, accounts for the rather forced amalgamation in his theory of the functions of respiration and expression.

But how does it happen that Bell omitted from his respiratory system the *intercostal* muscles and their nerves? One would think they had some claim to be considered as part of this great apparatus. They are constantly at work, and keep time with the diaphragm and lungs more steadily than any other outlying organs of respiration. But the intercostals are part of the regular symmetrical system of nerves, originating from the spinal cord, with double roots, and all the other features of their class. The author ignores this difficulty almost entirely, or alludes to it only so far as to surmise that the branches of these nerves which influence respiration are, "in all probability," derived from the same lateral tract of the spinal cord.[3] But there is not the least evidence adduced in support of this probability, and the assumption looks very much like reasoning in a circle.

The controversy once carried on as to the exact significance of Sir Charles Bell's doctrine and discoveries, was due in great measure to the singular obscurity of his style and his indefinite manner of statement. These defects were habitual with him as a writer, and in many instances are extremely marked. There are few pieces of harder reading than the preface and introduction to his *Nervous System of the Human Body*.[4] In attempting to account for this obscurity, the reader is sometimes left in doubt whether Bell really has any distinct idea to communicate, or whether he voluntarily stops short of its complete expression. One of these puzzling passages is the following. After speaking of the par vagum and the spinal accessory nerve, he says (page 47): "Directed in the next place to the portio dura, I wished to answer the question: Why does the nerve which supplies certain muscles of the face take an origin and a course different from the fifth nerve, destined to the same parts? *Guided by these considerations in my experiments, by inference I concluded* that on cutting across this nerve, all the motions of the face connected with respiration ceased, and that it had the origin we see, and took its course with the respiratory nerves, because it was necessary for the association of the muscles of the nostrils, cheek, and lips, with the other muscles used in breathing, speaking, etc." It is certainly impossible to determine from the phraseology of this sentence whether it contains the statement of an experimental fact or is only the expression of a hypothetical surmise.

Having enumerated again the various organs of respiration, he says (page 49): "It appears, then, that it is the distance and irregular position of the eye, nostril, mouth, throat, and larynx, and muscles of the neck, which require these diverging and apparently irregular nerves to connect them with the act of respiration, and without which they would have possessed no more attributes than the nerves of the limbs; that is to say, sensibility and motion."

There is nothing in the context to indicate from what point the eye, nostril, mouth, throat, and larynx are "distant" or why they should be considered as more "irregular" in position than the limbs.

One of the most curious instances of this peculiarity is a passage in one of Bell's earlier letters, describing his new system of the anatomy of the brain, and I think it hardly probable that any one now present will be able to understand exactly what he means by it. "I consider," he says,[1] "the organs of the outward senses as forming a distinct class of nerves from the other. I trace them to corresponding parts of the brain, totally distinct from the origins of the others. I take five tubercles within the brain as the internal senses. I trace the nerves of the nose, eye, ear, and tongue to these. Here I see established connections. Then the great mass of the brain receives processes from these central tubercles. Again, the greater mass of the cerebrum sends down processes, or crura, which give off all the common nerves of voluntary motion, etc. I establish, thus, a kind of circulation, as it were. In this inquiry, I describe many new connections. The whole opens up in a new and simple light; the nerves take a simple arrangement, the parts have appropriate nerves, and the whole accords with the phenomena of the pathology, *and is supported by interesting views*."

This indefinite style of expression extends, as in one of the passages just quoted, even to the description of experiments and their results. It is usually thought essential in reporting experiments, especially if bearing on new questions in physiology, to state all the particulars, so that the reader may form for himself some estimate of their value.

Bell habitually neglects this useful precaution. He generally omits all mention of the details of the operative procedure, often that of the species of the animal employed, and sometimes even whether it were living or dead at the time of the experiment. The consequence is, that doubts have been entertained on these points in regard to some of his most important investigations.

The truth is, Bell had no real faith in experimentation as a source of knowledge. He preferred to make his deductions in the first place from the details of

[1] Letters of Sir Charles Bell, p. 117.

anatomical structure; employing experiments afterwards to "prove" or "confirm" them, or to impress his convictions upon the minds of others. This is abundantly evident from his own express declaration in various parts of his work, as well as from the method he pursued in originating and carrying out his plans of investigation. With him, the conception of a system was the beginning and the end of the mental process; its experimental evidence was only an intermediate episode. For this reason, Bell would hardly be considered, at the present day, as a physiologist. Indeed, he never speaks of himself as such, but always as an "anatomist," whose whole pleasure is in "investigating structure;" and even his new doctrines and ideas he expressly designates as "discoveries in anatomy."

This explains, in some degree, his undue estimate of the two methods of inquiry. He had so high a regard for the results of anatomical research, that he believed them capable of also solving questions in physiology. Already, in 1808, three years before printing his *Idea of a New Anatomy of the Brain*, he "is sure," he says, "that he is correct," and that was before he had made a single experiment. And long afterwards he declared that the "few experiments which he has made were directed only to the verification of the fundamental principles on which the system is established." But the result of this method has been exactly the reverse of what he anticipated. The experimental observations which he undervalued form the only part of his system which has remained, while the attractive and harmonious classification, which he constructed with so much ingenuity on the basis of anatomical deduction, has now lost its importance and almost its place in medical literature.

The value of the experimental method in medical science cannot be measured by the direct results of any particular discovery. It is true that these discoveries are often of great importance, and increase largely the fund of our medical knowledge. They possess, moreover, a vitality which distinguishes them in a marked degree from the ephemeral products of scientific hypothesis. When a hypothetical system has served its time it disappears, and is replaced by a different one; but the knowledge derived from experiment remains serviceable long after its novelty has passed away. The experimental observations of Galen on the recurrent laryngeal nerves and on the function of the arteries as bloodvessels are as conclusive now as when he first made them, and retain at this day their full value. They have lasted for over seventeen centuries, and have survived during that time all the fluctuating medical systems of solidism and fluidism, of animism, vitalism, archaism, and iatro-mechanism. The information which they imparted was a reality, and is neither destroyed nor impaired by the lapse of time.

But the benefits of an experimental discovery extend far beyond its immediate limits. When a new fact has been established in anatomy or physiology, it is impossible to say what bearing it will have on other facts not yet discovered; and in the history of medicine there are many instances of curious observations which remained imperfect and apparently barren until subsequent discoveries invested them with an unexpected importance. It is evident that Galen's detection of the arterial blood-current in the second century was a necessary preliminary to Harvey's complete discovery of the circulation in the seventeenth; and the lymphatic vessels, discovered in 1651, were thought to be the agents of a slow and insignificant absorption, until Colin found, two hundred years later, that the daily quantity of fluids passing through the thoracic duct was from four to ten per cent. of the entire bodily weight. It is almost certain that a genuine investigation, however isolated at first, will produce, some time or other, its legitimate fruit. But to secure this object there is one essential requisite, and that is, that the experimental method be continued and cultivated for its own results, whatever they may be, without demanding or expecting immediate returns of a kind that can be designated beforehand, and with entire confidence that this method has always been, and will always be, the only source of permanent improvement in medical science.

ORIGINAL ARTICLES.

THE USE OF CONSTITUTIONAL REMEDIES IN THE TREATMENT OF EAR DISEASES.

BY SAMUEL THEOBALD, M.D.,

MEMBER OF THE AMERICAN OTOLOGICAL SOCIETY; SURGEON TO THE BALTIMORE CHARITY EYE AND EAR DISPENSARY; OPHTHALMIC AND AURAL SURGEON TO ST. VINCENT'S HOSPITAL, BALTIMORE.

(*Concluded from p. 129.*)

AND this brings me to the consideration of those very serious cases in which inflammation originating within the tympanum gives rise to intra-cranial complications, either by direct extension through the thin partition of bone which forms the roof of the tympanum, or indirectly by causing periostitis and caries of the mastoid antrum and cells. In the descriptions given of the treatment of mastoid disease in the works of Dalby, Buck, and Burnett, constitutional remedies (except the recommendation of anodynes by the last named) are completely ignored, and, singular as it may appear, the same is true of the works of Allen, of Tröltsch, and of Roosa. The "treatment of mastoid disease," as described by each of these authors, consists of little else than an account of how and when to perform Wilde's incision and to trephine the mastoid process. But are these, together with the application of leeches and fomentations, the *only* efficient remedies at our command with which to combat this dangerous malady? and must we say, with Dalby, that "where inflammation of the contents of the cranium has actually commenced, the issue of the case is certain?" I think not. If mercury is indicated in periostitis of the tympanum, it is certainly imperatively demanded (unless there be positive contra-indications to its use) when the periosteum of the mastoid cells, or the dura mater covering the roof of the tympanum, is involved in the inflammatory process. Of course, the stage which the malady may have reached when the case comes under observation, will have much to do in determining the propriety of the administration of mercury; but it may be well to utter a word of warning against deciding too hastily that the favorable period for its exhibition is passed, for, if we examine the many cases that have been published in which perforation of the mastoid was performed for the relief of intraosteal inflammation, we shall be surprised to find *in how few of them pus was discovered in the antrum or in the smaller cells;* of course, in a day or two it made its appearance, but how much had the traumatism to do with this?

We have seen in the case related by Dr. Buck what may be accomplished in meningitis dependent upon inflammation of the tympanum, by the timely administration of mercury; and, although I have been so fortunate as to meet with but very few cases of middle-ear disease complicated by serious intra-cranial or mastoid inflammation, I am able to furnish from my own limited experience at least two cases which forcibly illustrate the efficacy of this drug under such circumstances.

The first case, which occurred several years since, was that of a highly intelligent lady, about fifty years of age, of rather delicate constitution, and subject from early life to periodical attacks of severe headache, who

had an acute suppurative inflammation in the drum of the left ear, which resulted in perforation of the membrane and the establishment of an otorrhœa. To check this, powdered alum was blown into the auditory canal (a method of treatment which, under similar circumstances, I would not resort to with my present experience), and the discharge was arrested. Within a few days after this, pain, referred to the left side of the head, made its appearance, and presently mild delirium and well-marked aphasia. These alarming symptoms continuing, in spite of milder measures (which included the application of leeches and the liberal administration of bromides), with the approval of my grandfather, the late Prof. N. R. Smith, to whose wise teachings I owe much of the knowledge that stands me in best stead in dealing with both eye and ear diseases, and especially an abiding faith in the power of mercury to control inflammatory action, a seton was inserted in the left temple, and small doses of the biniodide of mercury,[1] to be taken three times a day, were prescribed. Under this treatment, which was kept up for a considerable time, an amelioration of all the unfavorable symptoms soon became manifest; and finally the aphasia, which persisted in a remarkable and most interesting manner for some time after the disappearance of the pain and delirium, vanished, and the patient's recovery was complete. And to-day she is in sound health, and in the possession of a brain which affords her an intellect of exceptional force and clearness. I should add that syphilis was certainly not an element in this case.

The other case is of recent occurrence—indeed, is still under observation. A man, twenty-three years of age, employed in an iron foundry in this city, came to the Baltimore Charity Eye and Ear Dispensary on the 7th of December, with hearing markedly impaired, and complaining of pain in the left ear. The right ear was blocked, and the left partially occluded, by impacted cerumen, the removal of which, however, did not by any means restore the hearing of either ear. The tympanal membrane of the left ear was opaque, thickened, and presented a sodden appearance; that of the right was somewhat dull, and not of normal translucency. My opinion was, that the deafness not relieved by the removal of the impacted cerumen, was dependent upon chronic middle-ear catarrh, and that the pain in the left ear, which he had felt at intervals for several weeks, was due to a more active inflammation in the tympanal membrane, or perhaps in the drum cavity, caused by the mechanical irritation of the impacted wax. I expected, therefore, that the removal of the latter would be followed by the quick subsidence of the pain, and was surprised to learn, two days afterwards, that there had been no diminution in it. The Politzer bag having been used (more especially to relieve an obstruction of the right Eustachian tube), an anodyne drop, to be instilled into the left ear, was prescribed, and the patient was directed to report in three days. When he returned at the expiration of this time (December 12), I discovered that the left mastoid region had become swollen, red, and very sensitive to the touch, and I learned that the pain, which was now chiefly post-aural, had increased greatly in severity. The appearance of the tympanal membrane, however, had undergone no appreciable change, and the Eustachian tube was pervious to the Valsalva method of inflation, the air entering the drum cavity with a dry, non-perforation sound. The true nature of the malady was now for the first time apparent, and I recognized at once that I had to do with an inflammation of the mastoid cells, evidently brought about by an extension into the antrum of the inflammation which started in the tympanal cavity.

Upon making this discovery, the patient was immediately placed upon biniodide of mercury, $\frac{1}{16}$ gr. to be taken three times a day, and four leeches were ordered to be applied beneath the auricle and just below the mastoid process, free after-bleeding to be encouraged. As there was no fluid in the tympanum, the membrane was *not* incised. Two days after this, although the pain had been relieved by the leeching, there was no improvement in the other symptoms; but, on the contrary, the redness, swelling, and tenderness of the mastoid had increased, a buzzing had begun in the left ear, and the muscles of the left side of the neck had become so sore and stiff that the patient carried his head as in torticollis, and could not, without great suffering, turn it to either the right or the left. If I had been *a thoroughly orthodox* aural surgeon, I certainly would have made, at this stage, a free incision over the mastoid, or perhaps would have opened the antrum. Instead of doing either, however, I gave the patient two powders, each containing four grains of calomel and ten of rhubarb, and directed him to take one at bedtime that night and the other on the following night, and, unless his mouth became sore, to continue the biniodide as before; and the wisdom of this course was made evident when the patient reported two days later (December 16), seemingly a different man,—his head no longer twisted to one side, the post-aural redness entirely gone, and the swelling and tenderness greatly diminished. He had taken the two powders, he said, the first one having acted quite freely upon the bowels, the second one less decidedly, and as he "had a bad taste in his mouth this morning," he had omitted the mid-day dose of biniodide. As there was no evidence of ptyalism, he was directed to resume the biniodide, and to take a third calomel and rhubarb powder at bedtime. On the morning of December 18, the soreness and stiffness of the neck had disappeared entirely, and no trace of the tenderness or swelling over the mastoid remained. The last powder had acted but once upon his bowels, and "yesterday morning," after taking the biniodide, his mouth had felt "a little sore," and he had not taken it since. The drums were inflated by Politzer's method, and he was told to resume the biniodide.

It is unnecessary to give a detailed account of the further progress of this case. Suffice it to say that, continuing the biniodide, commencing on the 23d to use a gargle of iodine and iodide of potassium, and the Politzer bag being used every day or two, he improved uninterruptedly until the 26th, when he indulged in a Christmas frolic—driving in a wagon six miles into the country, drinking "about four glasses of eggnog," and returning after nightfall. As a consequence of which he had for several days a slight return of soreness in the muscles of the neck, and an uncomfortable feeling in the back part of the head. As a precautionary measure, the dose of biniodide was increased on the 28th to $\frac{1}{12}$ gr., three times a day, and on December 31 he was feeling so well that he resumed his heavy work at the foundry, continuing, however, the mercury and the iodine gargle. January 6, he reported himself all right, except a scarcely perceptible tinnitus in the left ear, observable only upon lying down. He had suffered no inconvenience from the biniodide, and his work had produced no unpleasant results. The dose of mercury was reduced to $\frac{1}{16}$ gr. [To-day (January 8), he reports at my office for a careful examination. Since the use of the Politzer bag at his last visit, he has had no return of tinnitus, and he describes himself as feeling perfectly well in every way. The left tympanal membrane is rapidly regaining its normal appearance, and there is no depression of either drum-head. The left ear, which at one time, after the removal of the impacted cerumen, could distinguish

[1] I regret to say no written record of this case was kept, and I am not positive as to the exact dose in which the mercury was given; my impression is, however, that it was not more than $\frac{1}{16}$ of a grain.

the tick of the watch at only 2″, now hears it at 54″; and the right ear, which formerly heard it at but 20″, hears it to-day at 50″; while with each he can understand words and questions spoken in a whisper at 20′ with normal acuteness. Both Eustachian tubes are pervious to Valsalva, and no change in hearing, or perceptible alteration in the position of the tympanal membranes, follows Politzer's method of inflation. The biniodide (which he takes without the slightest inconvenience) and the gargle will be continued for some days longer, as a measure of precaution.]

And now, since my enthusiastic convictions regarding the value in diseases of the ear of the much-maligned mercury have led me to speak at such length of this one agent, I can only briefly allude to the other constitutional remedies which I have employed with advantage in aural practice.

From *iodide of potassium* I have not obtained the decided results which mercury has afforded me; nevertheless, in syphilitic affections of the middle and internal ear it may be substituted for the latter with undoubted advantage in some cases; and when middle-ear changes are associated with a rheumatic diathesis, it is, unquestionably, of service. It should be given in the same doses as when prescribed for other maladies. I have had no experience of the *heroic* method of administering it, but we have the excellent authority of Dr. Roosa for believing in its efficacy in specific inflammation of the labyrinth.

Allusion has already been made to *muriate of ammonia* as a useful remedy in mucous catarrh of the tympanum. Hinton recommends this agent in tinnitus.[1] I have no reason for thinking that it exerts a specific influence upon this particular symptom, but as I have very excellent reasons (from a somewhat extensive use of it) for considering it efficacious in subacute and chronic middle-ear catarrh, and as tinnitus is so often dependent upon one or the other of these conditions, I believe it does in this way frequently relieve this troublesome complaint. To adults I generally give it in ten-grain, sometimes in fifteen-grain, doses, dissolved in two drachms of water, four times a day, directing it to be taken in a little water; to children I give it in five- to eight-grain doses, and often add to the solution a small quantity of syrup of tolu. I would recommend it especially in the secretory or true form of middle-ear catarrh.

Another remedy to which I would direct the attention of those who are engaged in the treatment of ear diseases, is *pyrophosphate of soda*. For a knowledge of the virtues of this medicine I am indebted to Dr. Alan P. Smith. For a number of years he has employed it as an internal remedy in furuncular and carbuncular inflammation, in eczema of the auricle, or upon other parts of the body, and, indeed, in almost exactly the same conditions in which sulphide of calcium has been recommended. He regards it as a remedy of great value, and tells me he has frequently obtained very positive and unmistakable results from it. My own experience with it has not been very extensive, but I am sure I have seen it do good in furuncles in the auditory canal, and in acute suppurative inflammation of the middle ear, and I am certain I have seen hypopyon diminish under its influence—a crucial test of its powers. It should be given dissolved in water, in doses of from ten to twenty grains every two, three, or four hours, according to the urgency of the symptoms. It is not very soluble, so that in prescribing it at least half an ounce of water should be ordered to each twenty grains of the salt.

As to the efficacy of *sulphide of calcium*, of which Ringer speaks so decidedly, and to which Dr. Sexton has recently directed the attention of aural practitioners, I am not yet prepared to give a positive opinion. In some cases of furuncular inflammation of the auditory meatus, however, it has seemed to exert an influence for good which could hardly be doubted.

My experience with *arsenic* (Fowler's solution) in eczema of the auricle and auditory canal leads me to look upon it with more favor than some authorities are disposed to regard it. I consider it applicable, however, only to the chronic forms of this affection.

Almost all writers upon diseases of the ear have something to say concerning the usefulness of *cathartics*. Those which contain *calomel* are, according to my experience, the ones to which the aural physician may resort with the greatest confidence. I have inherited a partiality for a powder composed of calomel, rhubarb, and scammony (calomel, powdered scammony virg. āā 2–4 grs.; powdered rhubarb, 5–10 grs.); it is not a pleasant mixture to take, and with children and fastidious adults I sometimes give simply the calomel in two or three teaspoonfuls of syrup of rhubarb. Of the great good which may be accomplished by the administration of three or four such powders, at intervals of from twenty-four to forty-eight or more hours, according to circumstances, in very many cases of acute eczema of the auricle (especially that variety which we see so often in children associated with so-called *strumous* ophthalmia), of diffuse and furuncular inflammation of the auditory canal, and of simple and complicated acute otitis media, I do not need to speak with hesitation, as I have seen it demonstrated upon too many occasions.

It is scarcely necessary to allude to the value of *tonics* in many affections of the ear. I would, however, call attention to the excellent results which may be obtained from the *phosphates of iron, quinine, and strychnine in combination*,[1] in otorrhœa and in eczema of the external ear, especially when they occur in delicate children.

Although I have tried the various remedies which have been suggested at different times for the relief of tinnitus, such as *bromide of potassium*, *hydrobromic acid*, *ergot*, *belladonna*, *nitrite of amyl*, etc., I regret to say I have not obtained very decided results from any one of them. When this symptom is dependent *solely* upon hyperæmia of the labyrinthine vessels, the bromine combinations and ergot, especially, ought to exert a beneficial influence; in the more obstinate cases, however, this is, in all probability, not the usual, or at least not the sole cause, but there are others, such as anchylosis of the foot-plate of the stapes to the margin of the oval window, thickening of the membrane of the round window, etc., which, of course, are beyond the reach of such drugs.

As I have no especial suggestions to offer regarding the internal administration of *anodynes*, and as almost every work upon the ear commends their use when occasion requires, I will content myself with this brief allusion to them, and so avoid prolonging unnecessarily this already too prolix paper.

There is a tendency upon the part of all specialists —whether medical or not—*to become too highly specialized*. In the specialist who devotes himself to the study and treatment of diseases of the ear, the otologist, this tendency is manifested most conspicuously in a disposition to *over-estimate the value of purely local measures*, and to *under-estimate the value of constitutional measures*, in the treatment of the maladies with which he has to contend. In calling attention to this shortcoming of his, I believe I have not done a work of supererogation.

[1] Supplement to Toynbee's Diseases of the Ear. H. K. Lewis. London, 1868, p. 464.

[1] I employ a syrup prepared by Messrs. Sharp & Dohme, of Baltimore, containing in each fluidrachm, phosphate of iron gr. j, phos. quinia gr. j, and phos. strychnia $\frac{1}{32}$ gr., giving to children from 15 to 30 drops, and to adults one teaspoonful three times a day.

MEDICAL PROGRESS.

Heaton's Operation for the Radical Cure of Hernia.—In the *Boston Medical and Surgical Journal* for January 12, 1882, Dr. George W. Gay reports 15 cases of hernia in which he employed Heaton's method of injecting the fibrous tissue of the inguinal canal and ring with a preparation of white-oak bark, and applying pressure by means of a compress and bandage to keep the canal closed, and prevent the descent of the hernia until the contracted tissues become strong enough to support the strain imposed upon them. Of these cases 4 were cured; relieved, 8; not relieved, 3. Number of ruptures, 18; cured, 5; relieved, 8; not relieved, 5. Number of operations, 23.

With two exceptions, the above cases seemed to be favorable ones for the operation. That it was not more successful may very likely be due, in part, to the lack of skill and experience in the operator; in part to the imperfect after-treatment, especially in several instances, occurring in the out-patient department of the hospital; and, finally, to the fact that a second operation could not be obtained in several cases, in which not quite sufficient contraction resulted from the first.

While Dr. Gay does not feel justified from his limited experience, extending over only four years, in expressing a decided opinion as to the real value of the oak-bark treatment of hernia, yet his impression is that in the inguinal variety of the affection it is often a good method, and is worthy of further trial and study at the hands of competent surgeons. It would seem peculiarly adapted to cases with small rings, and to cases occurring in children, when nature herself is making a constant effort to correct the deformity, and requires but little assistance to enable her to accomplish the result.

Nothing is stated as to the merits of the operation in other kinds of hernia; but in the one under consideration it can be concluded that it is safe; it is not very painful; it is not very difficult to perform; it does little harm, even if it does no good; it will cure a certain number, and will relieve others.

Benzoic Acid in Rheumatism.—In acute articular rheumatism, Prof. Senator prescribes benzoic acid in preference to salicylic acid. He gives it in doses of from two and a half to three drachms, and benzoate of soda in doses of from three to three and a half drachms, daily. In more than twenty cases of which observations are reported, cure has taken place rapidly under the influence of these drugs, without complications or relapses. They are not, however, equally efficacious in subacute or apyretic rheumatism.—*L'Union Méd.*, Jan. 14, 1882.

Locomotor Ataxy in Sewing-machine Operators.—M. Guelliot has made a study of two cases of locomotor ataxy occurring in sewing-machine operators, and concludes:

1. That in cases of hysterical women, in whom a predisposition to locomotor ataxy exists, work on the sewing machine may occasionally be the cause of the development of the disease.

2. The symptoms appear first in the lower extremities, and gradually ascend. The darting pains occurring in flashes in the limbs from below upwards.

3. Under the influence of repose, a rapid improvement, which may be of long duration, is generally observed.—*L'Union Méd.*, Jan. 10, 1882.

Long Interval in the Birth of Twins.—Dr. Baranski reports the case of a woman who was easily delivered of an imperfectly developed male child and its placenta, and who, finding herself doing well, recommenced her ordinary house-work. While working in the fields, seventeen days after the birth of her child, a fresh discharge of liquor amnii occurred, unaccompanied by pains. Dr. Baranski was called to her the next day, found an arm presenting, and delivered her of a well-developed and unmacerated child. The placenta followed spontaneously.—*Centralb. f. d. Med. Wissen*, Dec. 17, 1881.

Relation of the Terminations of the Motor Nerves with Muscular Contraction.—M. Ch. Richet, at the meeting of the Société de Biologie, November 26, 1881, presented some facts which may serve to explain the rôle of the motor-nerve terminations in contracture and in the muscular function in general. When a limb, in a condition of contracture, is deprived of blood, the contracture disappears in from three to four minutes; the muscle, however, still remains excitable. The nerves also preserve their irritability longer than is generally supposed; to demonstrate this, it is necessary to experiment with the sensory, and not with the motor, nerves, since the motor plates of the latter being paralyzed, no effect could follow their stimulation; thus, in dogs in which the circulation is completely excluded from the limbs, sensibility may remain for from two and a half to three hours. It therefore follows, that if the nerve and muscle preserve their irritability for such a time, when the contracture rapidly disappears it must be due to a paralysis of the motor-nerve terminations, whose vitality resembles that of the nerve cells. In retarding the circulation in the arm by a rubber band, the voluntary movements become almost immediately feeble and irregular.—*Gaz. Méd. de Paris*, Dec. 10, 1881.

Diagnosis of Ataxia by Ocular Symptoms.—Given certain visual troubles, such as feebleness, binocular diplopia, paralysis of one or more muscles of the eye, etc., is it possible to diagnose in advance that the patient will become ataxic? That is the question which Dr. Sous (*Journ. de Méd. de Bordeaux*, 27 Juillet, 1881), endeavors to answer. He classifies the symptoms in two groups: 1. Those which are dependent upon an alteration of the optic nerve; and 2. Those produced by lesion of some other nerve.

Under the first heading, those which warrant a fear of ataxia, are the following: Gradual diminution of the acuteness of vision up to complete blindness, disproportionate to the evident ocular lesions. Further, the restriction of the field of vision commences at the outer borders, and progresses towards the centre. The pupil retains its form, but becomes grayish-white; there is also an alteration in the perception of colors, particularly for green and red.

As lesions of other nerves, the author mentions paralysis of the extrinsic muscles, especially those innervated by the third pair; sometimes there may be transient spasmodic contraction of these muscles. Strabismus is also mentioned, binocular diplopia, sometimes transient, sometimes permanent, and myosis, the pupil being fixed.—*Journ. de Méd. de Paris*, Dec. 31, 1881.

The Condition of the Uterine Blood-vessels after Parturition.—Dr. Balin has made a careful study of the changes in the uterine blood-vessels after delivery (*Archiv f. Gynaekologie*, Bd. xv., S. 157), and arrives at the following conclusions:

1. A part of the vessels of the uterine substance is obliterated by connective tissue; those remaining have their volume considerably reduced.

2. In the obliterated vessels, the tunica media is destroyed by fatty degeneration of its muscular fibres.

3. In the remaining vessels, the tunica media partially disappears.

4. The fatty degeneration of the walls of the blood-vessels commences later, and goes on more slowly, than the same process occurring in the muscular structure of the uterus.

5. A large number of capillary vessels of new formation are compressed by the uterine contractions which follow delivery, and are also absorbed or transformed by fatty degeneration.—*Journ. de Méd. de Paris*, Dec. 24, 1881.

PENETRATING PISTOL WOUND OF THE BRAIN.—In the *Boston Medical and Surgical Journal* for January 12, 1882, Dr. J. FOSTER BUSH reports the case of a boy aged sixteen, who was shot in the forehead one inch above the centre of the right eye, the ball, a number twenty-two conical projectile, entering the brain. After the accident he became comatose, the pupils dilated, the right not responding to light, the mouth drawn to the left, and the left arm and leg paralyzed for both motion and sensation. Seven months later perfect use of the arm and leg returned, the dizziness and headache disappeared, and, with the exception of some loss of memory, he appeared to be perfectly well.

DIAGNOSIS OF OVARIAN CYSTS FROM EXAMINATION OF THEIR CONTENTS.—Dr. GARRIGUES states that there is no element characteristic of myxoid ovarian fluid in the sense that a single hooklet is characteristic of a hydatid, but that by carefully weighing all the physical, chemical, and microscopical properties of the fluid, together with the other features of the case, a correct diagnosis is generally possible, while he knows of no character by which a cyst of the broad ligament can be distinguished from an ovarian cyst.—*Amer. Journ. of Obstetrics*, Jan., 1882.

RADICAL CURE OF HERNIA.—In a paper read by Dr. W. ALEXANDER at the meeting of the Liverpool Medical Institute, held December 1, he concludes:

1. That ligature of the neck of the sac, so as to obliterate the accidental or congenital depression, that was at once the predisposing and exciting cause of the hernia, offers by far the best methods of radical cure.

2. That other methods of cure are only effective in so far as they obliterate the sac up to its opening into the abdomen.

3. That methods of strengthening the abdominal supports too often fail if the sac is not obliterated, since the continuous pressure of the hernia on the unobliterated part of the sac will almost certainly neutralize and overcome any amount of cicatricial resistance that we are capable of generating in the surrounding tissues.

4. That after ligature of the neck of the sac, it is unnecessary to further disturb it except by incision to solve the continuity between it and the neck, and thus obtain better occlusion of the ligatured part.

5. That the operation, if carefully performed, is far less dangerous than the method of refusing to interfere with the cases upon whom the operation is justifiable.—*Liverpool Med. Chir. Journ.*, Jan., 1882.

ACTION UPON THE FŒTUS OF MEDICINES TAKEN BY THE MOTHER.—Dr. KUBASSOW (*Centralblatt f. Gynäkologie*) has employed the microphone to observe the condition of the fœtal heart, and thus to judge of the action upon it of drugs administered to the mother. He arrived at the following results: Chloral-hydrate and chloroform first excites and then stupefy, causing the fœtus to become quieter, and the heart-sounds duller and slower. They act in five or ten minutes, the action of chloral being more powerful than that of chloroform, and especially marked when given as an enema. Both of them can be detected chemically in blood from the umbilical cord. Chloral-hydrate depresses the temperature of the mother after two or three hours. Opium and its alkaloids caused distinct and persistent rhythm of the fœtal heart. They act more slowly than chloral and chloroform, and their action lasts longer. The opium acts more powerfully and quicker by the mouth than by enema. Its action probably depends on the morphia which it contains. Digitalis also acts powerfully and persistently. The author considers that the chloral-hydrate taken by the mother is divided between her body and that of the fœtus proportionately to the weight of each. This occurs in fifteen minutes, so that at the end of that time five per cent. of the chloral given to the mother has passed into the blood of the fœtus. The chloral-hydrate is not decomposed into chloroform. More than half a gram of chloral-hydrate in enema, either given at once, or repeated in less than half an hour, or more than fifteen minims of tincture of opium given at once, or repeated in less than an hour, are dangerous to the fœtus. Opium should not be given to pregnant women in doses exceeding a quarter of a grain.—*Practitioner*, Jan., 1882.

CONJUNCTIVAL TRANSPLANTATION.—M. MARC DUFOUR, in the *Revue Médicale de la Suisse Romande*, reports four cases in which he transplanted the conjunctival mucous membrane of the rabbit to the human eye. He operated in two cases of ocular symblepharon. The adhesion having been dissected away, a fragment of the mucous membrane of the rabbit's eye was applied to the denuded surface, and fixed in place by sutures. In an early case, that of an old woman, the operation failed; the fragment became necrosed, the woman being old. The fragments had been fixed with silk sutures. A little later the operation was performed on a child, aged eleven, and the transplanted fragment was fixed on the eye and the eyelid at the same time. The success was complete, and two months afterwards the fragment was quite living. In the case of a man, after the removal of an epithelioma of the eyelid, M. Dufour transplanted some mucous membrane taken from a small tumor on the lower lip of the patient himself. This operation was completely successful; nevertheless, it had to be followed a year afterwards by a fresh operation, the disease having recurred. This time, also, a fragment of the mucous membrane of the lip was taken. M. Dufour recommends that the transplantation should not be made too soon after the incision; that the fragment to be transplanted should be previously fixed with sutures to prevent the rolling up of the edges. He recommends that the revivified place and the fragment should be washed with salicylic acid.—*British Med. Journ.*, Jan. 14, 1882.

POLYPI AND EXCRESCENCES OF THE FEMALE GENERATIVE ORGANS.—According to the clinical and anatomico-pathological researches of M. FORGET, the urethral mucous membrane may exhibit three distinct conditions:

1. Papillary hyperplasia, which is very frequently observed, and which gives rise to granular vegetations, a number being usually conjoined, while the true polypus is generally single.

2. The true polypus, or fibrous neoplasm, is usually attached to the mucous membrane by a pedicle.

3. Simple hypertrophy of the mucous membrane by which a prolapse, resembling somewhat a polypus, is formed.

M. Forget also believes that whenever there is a permanent spasm of the urethra, the intense congestion resulting is a sufficient irritation to produce fungoid growths.—*L'Union Méd.*, Dec. 25, 1881.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, FEBRUARY 18, 1882.

PROGRESS OF SANITARY ORGANIZATION.

THE progress of sanitary organization in the United States is one of the marvellous features of our civilization. Scarcely a quarter of a century has passed since the first ripple of agitation was set in motion by Jewell, of Philadelphia. At that period, 1856, the purposes of sanitary organization in civil administration were either unknown or altogether ignored. The first call for a National Sanitary Conference fell upon dull and credulous ears, and it was only as a Quarantine Convention that the movement gained popular favor. But from the moment that the first Convention began to discuss the great questions of quarantine, and allied subjects, May 13, 1857, sanitary reform took deep and abiding root in the public mind of this country. The second Convention was an enthusiastic gathering of officials and laymen, and sanitary questions naturally became the leading topics of discussion. Two more annual Conventions met, each being more and more largely attended, when the civil war absorbed for the time the interests which this great popular movement had created.

In 1865–6, the agitation was renewed by a fierce struggle between the medical profession of New York and the notoriously ignorant and corrupt political organization which controlled the health department of that city. The average intelligence of its officers appears in the answer of one of the health wardens to the official inquiry, "What is hygiene?" The prompt reply was, "The mist which rises from stagnant water." So wide-spread was this agitation that not only did all ranks of citizens of that city become profoundly interested in the result, but other cities, especially Chicago, Washington, and New Orleans, were stimulated to action, and entered upon similar crusades against their inefficient health organizations. In 1866, the contest in New York culminated in the passage of the Metropolitan Health Bill, the most perfect sanitary act ever placed upon the statute-book. This law has furnished the text for much of the subsequent sanitary legislation in this country. The Metropolitan Board of Health was confronted, immediately on its organization, with Asiatic cholera, but so successfully did it deal with the first outbreak of that pestilence that public apprehension was allayed, and the Health Department became the most popular branch of the city government, a position which it has steadily maintained for sixteen years. From this period the agitation for sanitary reform took a new departure, and spread to the most remote parts of the country.

In 1869, the State Board of Health of Massachusetts, after prolonged opposition, struggled into existence, and in the following year the State of California organized its State Board. In 1871, the States of Louisiana and Michigan established State Boards of Health, and in the following year the States of Minnesota and Virginia followed their example. The year 1872 is memorable for the organization of the American Public Health Association, a body which at first consisted of a few earnest laborers in different sanitary organizations, but which now comprises a membership of upwards of six hundred persons, embracing the leading thinkers and workers in the field of State medicine. This Association, meeting annually in conference upon the current questions in sanitary science and administration, has exerted a large and most salutary influence. To its annual discussions, so widely published, we must attribute much of that popularization of subjects relating to public hygiene so essential to the thorough organization of sanitary government, and its successful administration. It has stimulated new scientific inquiries, has sustained feeble and wavering health authorities, has aroused popular thought, and awakened an interest of communities in the insanitary conditions under which the people live. During the decade of its existence sanitary organizations multiplied with unexampled rapidity throughout the country, no less than twenty-two additional State Boards, making twenty-eight in all, being established during that period. The crowning event, however, was the organization of the National Board of Health, which gave completeness and perfection to the scheme of sanitary government in this country.

We have made this brief review of the progress of sanitary organization not so much for the purpose of congratulating the medical profession upon the brilliant future which evidently awaits State Medicine in the United States, as to encourage and stimulate

to greater endeavor. The present time is exceedingly favorable for popular agitation of public health questions, and for effort to secure sanitary legislation. Popular lectures on hygiene attract large and thoughtful audiences during the winter months, and do more to stimulate thought and action among the people than any form of printed matter. Every physician can give two or three lectures on sanitary subjects to the community in which he resides, which we know from experience will attract larger numbers than the lectures of popular speakers. Again, at this season State Legislatures are generally in session, and the occasion is favorable to obtain necessary legislation. Though twenty-eight States have organized State Boards of Health, yet the great States of Pennsylvania, Ohio, Missouri, Texas, and the old New England States Vermont and Maine lag in the race. With suitable effort on the part of our profession, there is no doubt that in every remaining State boards of health can be established during the coming year. When this most desirable consummation is reached, the United States will present an example of sanitary organization hitherto unrealized in modern civilization.

THE NEW YORK STATE MEDICAL SOCIETY, AND ITS NEW CODE OF ETHICS.

IN our last issue we published the new code of medical ethics adopted by the New York State Medical Society. We observe, with extreme regret, that this representative and influential organization has committed itself, in this act, to regulations in antagonism to the code of the American Medical Association, and has placed its membership in a position which we believe to be essentially false and illogical. Under the head of "Rules Governing Consultations," it is declared that "members of the State Society, and of the medical societies in affiliation therewith, may meet in consultation legally qualified practitioners of medicine," and that "emergencies may occur in which all restrictions should, in the judgment of the practitioner, yield to the demands of humanity." A "*legally qualified practitioner*" is one possessed of a diploma from some duly incorporated medical college, and he may "trade under any special designation," as homœopath, eclectic, physio-medical, or other term, which may be best for his interests. That there may be no possible misconception of the latitude thus allowed, "all restrictions" may yield, in the sole judgment of the physician concerned.

Trading under a special designation has, recently, been formally condemned by the Royal College of Physicians, of London—the purest conservator of professional dignity and morality in the whole medical professional body. The New York Society condemns with pragmatical particularity such offences as publishing handbills, private cards, and advertisements, the details of cases, and opinions on points of medical or surgical practice, inviting laymen to be present at operations, and the boasting of cures, and remedies, etc., and yet, in a line or two, opens the door to the most reprehensible of all practices, viz., consulting with practitioners who owe their success to the use of some special trade designation. Dr. Jacobi, the President, in his prelusive address, prepares the way for the revolutionary code of ethics, but without committing himself to it, by stating that if "the profession of the State of New York are sufficiently imbued with that spirit of logic and experimental science, we may overlook differences, and meet, with a spirit of reconciliation, those who do not encounter us any more with the dicta of a school or sect." The Code of Ethics does not assume even such a conservative position, but makes haste to surrender every principle for which the regular profession has heretofore contended. There has been on the part of regular physicians no spirit of proscription against those irregulars who would abjure their special creed and trade designation, and rank themselves as physicians only. The warfare has been, not against the consciences of men, not against the right to treat diseases according to their convictions of the utility of therapeutical measures. It is the parading of a special designation, the offensive proclamation of "*similia similibus*," as the trade insignia, against which the great body of the medical profession has protested, and will continue to protest. All the glittering generalities which are now uttered to conceal the real point at issue, the authority of great names, and the momentary outburst of a humanitarian sentiment in a great medical society, will not blind the thinking men of the profession.

To yield the point, of the right to consult with all kinds of irregulars who happen to be "legally qualified practitioners," is to admit that the regular medical profession has hitherto occupied a false position.

To yield the point, is to admit that they who have maintained the truth of an exclusive dogma, and have practised on a trade designation, were right, and those who opposed them were wrong.

To yield the point, is to strengthen all irregular practitioners in their position of bigoted intolerance, and to confuse and dismay the disciples and friends of legitimate medicine.

We do not believe that the medical profession will thus stultify themselves, but that they will more energetically than before reaffirm the great principles for which they have steadfastly contended.

In some future issue we will set forth more specifically why legitimate medicine *cannot* consort with those who trade under special designations.

FORCED ALIMENTATION IN CONSUMPTION.

THE attention of our readers has been drawn to the method of forced feeding of consumptives. The loud acclamations with which the new expedient has been received have hardly died away when some accidents are reported. M. Desnos, whilst admitting the good which may be thus effected, reports a case in which bad results followed. The patient had tubercular excavations in both lungs. After the milk was deposited in the stomach by the tube, a violent attack of dyspnœa occurred, and the patient expectorated milk. Pneumonia came on, and death ensued in thirty-six hours. At the autopsy, the lesions of tuberculosis and of a recent pneumonia were found, and the milk filled the trachea up to the larynx. Also, M. Bariot, *interne*, of Charité, has published three cases of absolute intolerance of the method. In some cases diarrhœa results. Nevertheless, M. Desnos continues to advocate the method, advising certain precautions. The liquid (food) should not be given during the febrile exacerbations, and should be introduced slowly.

M. Ferrand reports a case of hereditary phthisis advanced to the third degree, in which forced alimentation produced a marked improvement from May to July; but then the patient retrograded, notwithstanding the method was persisted in, and died in November.

Further clinical experience is necessary before deciding on the value of the new expedient.

A BUREAU FOR NURSES.

FEW people who have not tried it, know the difficulty and delay experienced in procuring a nurse. Sickness and accident always come unexpectedly, and the nurse is wanted instantly. How is one obtained? The ordinary process is to get a list from the doctor, and then make, afoot, in car, or in carriage, a weary pilgrimage for an entire day, not seldom two, and sometimes three, before one can be had, and then we have to be satisfied with what we can get, rather than what we wish to get. The Woman's Hospital Training School, and the Nurses' Home, excellent as they are, can only furnish one of their own pupil nurses when she happens to be there, or occasionally a graduate. And yet, at the very moment when the patient is anxiously seeking a nurse, scores of good ones are waiting a chance to earn a living. What we need is something to bring together the two classes.

Boston has done some very good things, and in the nurse matter two years since took an important step in advance. The Medical Library Association appointed a committee to manage the affair, in conjunction with a committee of ladies interested in the various training schools, after this fashion: Their Assistant Librarian, who lives on the premises, is the Secretary, and keeps the Directory. A nurse who registers gives references to several physicians and families with whom he or she has nursed. If the replies to the inquiries which are made are satisfactory, the name and address are registered after the payment of a small fee, together with the qualifications, charges, what kind of nursing is preferred, whether he or she will nurse in contagious diseases, insanity, etc. This record is afterwards added to by inquiries of every doctor and family who obtain the nurse's services. A register is then kept of all engagements, whether made through the Directory or not, and the nurse is expected to keep the Secretary informed of every engagement taken, and again when it is terminated, in order to keep it perfect to date. Any one, then, going to the office, day or night, with or without such a list of nurses, can be accurately and instantly informed who are engaged and who disengaged, their qualifications, terms, etc.; or, if desired, by letter or telegram, the Secretary himself will secure and send a nurse as quickly as possible. Wet nurses, in many cases certified as to good health, nurses for the insane, etc., can also be had. It is evident that as the advantages of the system become known, the increasing patronage, both of nurses and patients, will be mutually advantageous, in adding to the number, and especially in bettering the quality of the nurses, and the more competent nurses will obtain more frequent employment.

Financially, also, it has proved a decided success, even from the start, inuring thus to the advantage of the Library. In Boston 412 nurses, of whom 46 are men, are now on the register, and the monthly average of nurses furnished last year was 74. Many of them were obtained by telegraph all over the New England States, and sometimes even from greater distances. One instance of premature confinement, when the pre-engaged nurse was unable to come, shows well how quickly the want may be supplied. Within an hour after the telegram was sent, a nurse had been found, made her preparations, and was at the patient's door, five miles out of the city.

We are glad to learn that the College of Physicians of Philadelphia lately has appointed a committee to consider the feasibility of establishing a similar Bureau in this city, and we hope most earnestly that it will be established, and that the profession will give it a unanimous and hearty support, both by advising their nurses to register, and in turn by sending patients to the Bureau to secure such nurses. The College having already a local habitation, is pre-eminently the body to establish such a system, and with a generous support from the members of the County and other Medical Societies and the public, it will become here, as it has in Boston,

one of the most useful and most successful advances that has been made.

CONDITIONS UNDER WHICH OXYGEN IS A POISON.

PURE oxygen inhaled for three days determines, in mice, fatal congestive and inflammatory pulmonary lesions. If the animals are removed before the expiration of three days, the pulmonary accidents are not necessarily fatal, and their intensity is more or less related to the duration of the oxygen inhalation, in dogs as well as in mice.

Injected into the veins, pure oxygen proves fatal to dogs whenever the tension of the injected gas, irrespective of its quantity, is equal to the muscular strength of the right heart. Injected into the arteries in the smallest proportion, oxygen gives rise to serious nervous symptoms, often fatal, dependent on gaseous embolisms. The lesions vary from a simple ischæmia, up to hæmorrhages and acute softening, indicating an obstruction of the capillaries by elastic, gaseous columns. Breathed in a state of high tension, pure oxygen is a poison, as has been established by the remarkable researches of Paul Bert, confirmed by the experiences of M. Feltz. Under all circumstances, the action of oxygen is exerted on the nervous system.

Notwithstanding that oxygen may, under some circumstances, prove a poison, it is, under many others, a most useful remedy. In the asphyxia produced by the inhalation of cesspool gases, it affords prompt relief, by renewing again the function of the red globules. In many kinds of dyspnœa, it is the most rational remedy. When the respiratory organs are unable to obtain a sufficient supply of air, although exerting their utmost efforts, the inhalation of oxygen at once relieves the distress. Quebracho is supposed to blunt the sense of want of air, but oxygen relieves it by furnishing the required material. Quebracho, then, merely renders the patient insensible to the source of distress, whilst oxygen removes the cause of it. For many cases of dyspnœa, oxygen is superior to its newest rival. Oxygen, again, has an important office in improving the condition of the blood in anæmia, chlorosis, and allied conditions.

THE CARTWRIGHT LECTURES.

IN our present issue we complete the publication of the admirable lectures of Dr. Dalton "On the Experimental Method in Medical Science." We congratulate our readers that they are able to find in THE MEDICAL NEWS, on the week of their delivery, these important contributions to the history of physiology. In all that concerns the historical development of physiology, Dr. Dalton is, of course, a master. It is most timely to have brought before the profession the history of the remarkable extension which the experimental method has given to physiological science. Now, when ignorant enthusiasts are trying to destroy the most important means for contributing to the growth of this science, should be marshalled in order the vast array of facts and principles which but for the experimental method had remained unknown. It is, also, but just to the great experimentalists of the past, that we recall their achievements, and apportion the merit as it is deserved. In the ever-enlarging annals of discovery, the exact share of each worker in the results attained is apt to be overlooked or forgotten, and thus it often happens that supposed discoveries are but revivals of former achievements. We owe, then, our thanks to Dr. Dalton for the historical data of physiology which he is placing so lucidly and completely before us. And we have again to congratulate the Alumni Association of the College of Physicians on the bequest of Mr. Cartwright, which is enabling them, annually, to have delivered a course of lectures which, we may hope, will equal those which have for so many years contributed so much to the renown of English medicine—the Gulstonian, Lumleian, and other lecture courses. It is to be hoped that the example of Mr. Cartwright will be followed by other wealthy men, who may thus perpetuate their names in connection with a worthy and useful purpose. The Cartwright lectures were inaugurated last year by Dr. Bartholow, of Philadelphia, who gave a course of six lectures on "The Physiological Antagonism of Medicines and between Remedies and Diseases."

THE DOCTOR HIS OWN PHOTOGRAPHER.

MEDICAL men very frequently want photographs in cases of injury, deformity, tumors, etc., but the trouble and expense have been serious bars to obtaining them; and many patients, too, cannot go to the photographer. Drawings are often even more expensive, and always labor under the disadvantage of possible inexactness. Recently, however, the introduction of the "dry-plate" process has so simplified the method, avoided the former dangers, and reduced the expense, that any one of ordinary intelligence and means can now take all the photographs he wants at a moment's notice. At the Cincinnati meeting of the American Association for the Advancement of Science last August, Mr. Walker, of Rochester, New York, showed a "pocket camera," which, according to Prof. Lattimore, supplies every want of the inexperienced amateur. Its weight is only two pounds. "Dry-plate outfits" are now to be had at a cost of $10 and upwards, which are excellent. Provided with one of these instruments, the doctor would always be prepared to photograph any case he desires, at his office or in the sick-room. Our hospitals, especially, should be provided with

such a good outfit, so that cases and specimens could be photographed at any time, even by a resident. Our microscopists would also find it exceedingly useful to make permanent many a transient preparation not suitable for preservation.

NOTE ON NERVE-STRETCHING.

DR. G. LUDWIG writes to the *Lancet* of January 7, detailing a new method of nerve-stretching without the knife, or subcutaneous nerve-stretching, which, in the hands of Nussbaum and Billroth, seems to have given good results. It consists in narcotizing the patient, and then forcibly flexing the femur against the abdomen, so as to stretch the sciatic nerve round the neck of the femur. The method is well worth a trial, and may be, perhaps, of great value, but we must point out one error which may easily be committed in adults. If the femur be flexed up to about 40° or 45°, with the lower leg in extension, all is well, but at that point the hamstrings are put in complete tension, and beyond it they must be over-stretched and ruptured to a greater or less extent, while the narcotized patient cannot feel the pain, and so warn us that in stretching the nerve we are damaging the muscles. By flexing the leg we relax the hamstrings, and avoid the danger. How much this may relax the nerve, too, and so vitiate the nerve-stretching, is a question.

REVIEWS.

RHEUMATISM; ITS NATURE, ITS PATHOLOGY, AND ITS SUCCESSFUL TREATMENT. By T. J. MACLAGAN, M.D. 8vo, pp. 333. London: Pickering & Co., 1881.

Since March, 1876, Dr. Maclagan has been known as the prophet of the salicin treatment of rheumatism. Before his earliest publication appeared, Stricker announced that salicylic acid had been used by himself and others in Germany with great success (*Berliner klin. Wochen.*, Nos. 1 and 2, 1876). Maclagan has continued to maintain the superiority of salicin, and has invented a theory of rheumatism to account for the success of his remedy. The book now before us is the result of this conflict. It treats of the natural history of rheumatism, of the nature of the rheumatic poison, of the lactic-acid theory, of the miasmatic theory, of the nature and action of malaria, and of the various plans of treating rheumatism. The special motive of the book is to show the relationship between rheumatic fever and intermittent fever, and to refer the origin of both to *malaria*.

In his discussion of the various theories of rheumatism, our author begins with the lactic-acid theory. He finds that there is in this disease a great increase in the formation of lactic acid, and also in its elimination; but he "rejects its claim to afford an adequate explanation of the phenomena of rheumatic fever." He believes, nevertheless, that the presence of lactic acid is a necessary element in the morbid complexus, but a result rather than a cause. There is, he admits, no other product of tissue metamorphosis to which the rheumatic symptoms can be ascribed; he therefore seeks to find the morbific cause, the pathogenetic material, without the body. He finds this in malaria. There is a remarkable correspondence in the phenomena of a rheumatic and of an intermittent fever attack, according to our author. He holds to the miasmatic origin of rheumatism, and to the identity of the malarial and rheumatic poisons. The outcome of his reflections on the appropriate treatment of the rheumatic miasm was salicin. Observe his ratiocination: "A low-lying, damp locality, with a cold rather than warm climate, are the conditions under which rheumatism is most likely to arise. On reflection, it seemed to me that those plants whose haunts best corresponded to this description, were those belonging to the natural order salicaceæ—the various forms of willow. Among the salicaceæ, therefore, I determined to search for a remedy for rheumatism." Could any premises and conclusions be stuffed fuller of fallacies? He did not find his best antimiasmatic remedy in quinine, which had been fully tried, but in salicin, whose derivative, salicylic acid, had already become well known as a most efficient remedy for rheumatism. Nothing is easier than to prophecy after the fact.

Dr. Maclagan believes that the "whole of the salicyl series is possessed of antirheumatic properties," but that "salicin and salicylic acids are the two which are at once the most easily obtained, and the most convenient for administration." The largest possible doses are necessary, for "the rheumatic poison is a minute organism, which is propagated in, and acts on, the fibrous tissues of the motor apparatus of the body," and "the salicyl compounds act by destroying this poison, but for its destruction a certain quantity is necessary." He concludes that salicin is preferable because it is safer in the considerable quantity necessary. He apparently ignores the important fact that salicin, in its passage through the body, is converted into salicylic acid.

The salicyl compounds, our author thinks, "cannot fail to prevent cardiac complications *if given in sufficient quantity to destroy the rheumatic poison before this has begun to affect the heart.*"

With some fact there is much theory of a very unsubstantial kind mixed up in this book. Nevertheless, it contains much suggestive matter, is very readable, and is an attempt to set forth novel views divorced from the errors which have prevailed for several generations.

> "'Tis neither antiquity nor author
> That makes truth truth, although time's daughter."

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 2, 1882.

FORDYCE BARKER, M.D., PRESIDENT, IN THE CHAIR.

The Society was called to order at 8 P.M. After the reading of the minutes of the preceding meeting, Dr. JOHN G. ADAMS, Corresponding Secretary, announced the death of the following foreign, distinguished medical gentlemen:

THEO. SCHWANN, of the University of Louvain, Belgium, who was the discoverer of the primordial cells in animals and plants, and a distinguished microscopist.

M. BRIERRE DE BOISMONT, distinguished as a writer on medical jurisprudence. Died in Paris at the age of eighty-one years.

SIR ROBERT CHRISTISON, author of a treatise on poisons, and Professor of Medical Jurisprudence in the University of Edinburgh.

Dr. BOUILLAUD, the last of the distinguished men who made the Paris School of Medicine so famous fifty years ago. Author of a work on diseases of the heart.

Died the latter part of October, 1881, at the age of eighty-three years.

The PRESIDENT then made an introductory address as follows:

One of the avowed objects of this Academy, as expressed in its constitution, is the promotion of the public health. Strictly speaking, all of our scientific work is in this direction, but this meeting is, in a larger sense, devoted specifically to this object.

There is not a physician in this city, engaged in active practice, who is not frequently called upon to see disease of various degrees of severity, often resulting in death, which has been caused by a poison. If we can see our patients early enough, we can successfully meet such poisons as arsenic, as corrosive sublimate, as aconite, and all of this class, because we have antidotes which will prevent their effects. But where the poison is introduced into the system so insidiously that the subject is unconscious of its absorption until its effects are produced, then it is not a question of antidotes, but the problem is, how shall we counteract its consequences, and how shall we keep our patients alive until the life-destroying agents have ceased to put in jeopardy the vital powers?

The special poisons to which I now refer, are the gases resulting from defective plumbing, to which all classes—the poor occupants of tenement houses, those who are able to command the necessaries and many of the luxuries of life, and those who live in the most expensive houses, and whose riches can buy everything but health—are alike exposed. None but physicians can know how general this poison is, and how positively it explains much of the disease that they are called upon to treat, and of the many sad deaths which follow.

When I assert that it is a daily experience with me to see persons whose general health is suffering from this poison, as is manifested by malaise, loss of appetite and strength, slight febrile symptoms, diarrhœa, physical and mental depression; and that I have seen infants, children, and adults suffering from diphtheria, scarlet fever of a mild type complicated with this disease, and destroying life; those in vigorous health, students in colleges, ambitious and active young men in the professions or in the commercial or financial world stricken down by typhoid fever, some struggling through the disease, and others dying, and that the cause has been demonstrated to be this poison, I only state facts which are common in the experience of all physicians in this city. In some cases this has been the result of ignorance of the very sanitary conditions which environed them. For example, two young men were stricken with typhoid fever, one of whom died. They were not acquaintances, but occupied offices in the same building in the vicinity of Wall Street. On investigation, it was found that there was not a trap in the whole building.

In a house, in which but a few months before several hundred dollars had been expended to put the plumbing in perfect condition, a young man died of typhoid fever, others of the family became ill, when it was found that a defective waste-pipe was saturating the house with poisonous gas. But such facts as these are so common and so well known to the profession, that I need not dwell upon them.

It is the custom of many in this city, whose means will permit them to do so, to take their families for health and pleasure to various summer resorts, at the seaside, the mountains, and other attractive country hotels, but every year, for some time past, some of these places have proved fatal to health, and often to life, by typhoid fever, so that now it seems to be the plain duty of every physician to warn such families as hold him responsible for their health, of the danger of every such resort that does not give them the evidence of a competent sanitary expert that their house is safe from all such dangers.

None but physicians are alive to the fact that many of those now living in beautiful and expensive houses in this city are like the inhabitants who dwell at the base of Mount Vesuvius, in a soft, balmy, voluptuous atmosphere, surrounded by vineyards and gardens luxuriant with the olive, and the fig, and the orange trees, which mask and hide the danger and desolation of the lava and ashes. It is absurd to suppose that those who find pleasure in expending many thousands in buying, and art to embellish their home, will not gladly expend the insignificant sum necessary to make their homes healthy for their families and themselves.

The physician should never be an alarmist; he never can hoist the signal of danger, except when he sees the forewarning signs of an impending storm. Unfortunately, he never can see the danger from this poison until its effects are already beginning to develop, as shown by the disease. Then, again, he labors under the difficulty of being unable to demonstrate, or even suggest, where the poison originates. He can only say that science has established the fact that certain symptoms are due to certain causes. It seems to me that it is the duty of the profession to educate itself up to the point of being able to demonstrate intelligently to patients how the danger from these poisons may originate.

The PRESIDENT then introduced Mr. CHARLES F. WINGATE, who proceeded to read the paper of the evening, entitled:

Practical Points in Plumbing—Knowledge Necessary for Physicians for the Protection of their Patients.

He said that it seems like carrying coals to Newcastle to offer advice to medical men regarding sanitation. Yet, as the old derisive proverb has been set at naught by "the whirligig of time," so it has strangely come to pass that the sanitary engineer can now assume to instruct his betters, and even show physicians their omissions in matters properly within their province.

He, therefore, limited his remarks to the practical points relating to plumbing, and kindred subjects which have a direct relation to the physician's efforts to overcome disease. When so much sickness can be traced to unsanitary conditions due in the main to preventable causes, it is desirable that the family physician should be able to point out such conditions, and in a general way suggest the proper remedies for them. When, also, so much foolish fear prevails regarding the risks to health from so-called modern improvements, the physician should be able not only to assure, but to convince his patients, that plumbing properly executed with good materials, and upon scientific principles, is absolutely safe, and is decidedly to be approved rather than abolished. Plumbing appliances are hence no more deserving to be done away with than are gas or electricity, the railway or the newspaper, each of which is also open to serious objections. Whenever sickness, such as is usually traceable to defective plumbing or drainage, prevails in a house, and no sufficient cause for its existence is apparent, the physician should not be content until an examination has been made by a health officer, or other competent person, to make sure that the house is free from sanitary defects. Nothing should be taken for granted in such matters, and no evidence accepted regarding the safety of hidden plumbing work, as underground drains, cesspools, traps, etc., except to have them open to view, and their real condition proved beyond a doubt. Every physician should warn his patients not to lease or buy any dwelling, whether old or new, without having the premises thoroughly examined, and obtaining a certificate of their healthfulness; not the ordinary landlord's or agent's verbal statement that everything is lovely, etc., but a legal document that will hold good in the courts,

and be a ground for obtaining damages in case the house should prove to be unsanitary, and sickness result in consequence. This wise precaution is now being taken by many persons. The examination, however, must be thorough, or it will be useless, as a false sense of security, based upon an incomplete examination, is worse than absolute ignorance.

The first point is how to examine a house. In this examination, nothing should be taken for granted. Every part of the plumbing must be exposed to view, or tested. The peppermint test is one of the best for detecting defective plumbing. An ounce of peppermint in a pail of water is poured into the openings of the plumbing fixtures at the upper part of the house. If the smell of peppermint escapes by a leak, this shows that sewer-gas would also escape. A second point is the quality of the details of the plumbing work. A single portion of the work, one joint of pipe, will tell a practised plumber the capacity of the workman. If a house is deficient in its minor details, it will be found generally bad. A direct leak from a pipe will be shown by holding a candle near it. The practised nose can tell a leak in a short time, and by the density of the smell from a roof-pipe, it can be learned whether there is a trap in the pipe to the sewer. The sanitary engineer goes first to the cellar and looks at the sources of damp. These are manifold both in the city and country; rain and snow blow in; there is leakage from the water-pipes and areas, and there is the refrigerator waste.

Another source of danger is from broken or leaky underground drains. Most houses have underground drains which are made of tiles laid by ignorant workmen, and he had seldom or never found a drain which was not in a defective condition. In Boston he had found many drain-pipes without the proper pitch or flush. Some pitched towards the houses instead of the sewers; others were choked with grease, or there were no sewer connections at all. The plumber sometimes ran the drain over a rock, up and down, or ended it on one side, continuing on the other, or connecting two sections of six-inch pipe by a four-inch pipe. A break or stoppage meant a deadly deposit of sewerage. An important question arose as to the legal responsibility of owners for damages from sickness. The courts had lately decided, that if the landlord is cognizant of sanitary defects, he is liable for resulting injuries. Nothing but iron pipes with lead joints properly coupled, and carried along the cellars in sight, or in trenches easily accessible, should be used.

Another source of danger was from the enormous quantity of made land in cities. The New York Board of Health states that ten years are necessary to thoroughly purify made land.

Down to a very late date, many of the sewers of New York were constructed of inferior material and imperfectly laid. Badly-burned bricks, bogus cement, and sand that was half loam, were used in making them, while many times the contractors who laid them executed their work in the cheapest and most culpable manner. Few of the best sewers were really tight, while the majority leaked at every joint, and thus the whole system was an enormous source of soil pollution. From the lack of a comprehensive plan in the beginning, and of competent supervision during their construction, many of the sewers had little, or not enough, grade, and were not easily flushed. Hence, they become (especially when tide-locked) elongated cesspools and mere gasometers for creating evil. Their lack of ventilation leaves small chance for the sewer-gases to find vent, excepting through the house-drains, and the average plumbing affords no barrier against their free diffusion throughout living- and sleeping-rooms. And here it should be remarked, that sewer-gas is created not only in the sewers alone, but every inch of waste-pipe in a house, even though used to convey nothing but soapy water, or the waste of melted ice from a refrigerator, can and commonly does produce foul gases. The worst odors are from just such sources, and they are certainly unwholesome. There are many broken gas-mains. The soil can hardly be dug up without encountering the smell of gas. The gas companies are aware of this loss, and make it up in their bills. Prof. Chandler says that ninety per cent. of the cellars in New York are bad, and the speaker would say that ninety-five per cent. are either originally dangerous or made so by neglect.

There were several sources of foul air in houses. The air supplied to the furnace is often taken from the cellar, or the cold air-boxes are made of unseasoned wood, and in them rats, cats, and chickens seek shelter. In one house two chickens and a cat were found roasted in the brick work near the furnace. The refrigerator should have no connection with the drains as they are built in most houses, nor should the refrigerator waste run into the soil. Garbage and dust from wet and coal in cellars cause foul air, which is drawn up into the living-rooms by the suction of hot air, if not through the dumb-waiters. It is desirable to have the kitchen and laundry separate from the house. The servants' accommodations should be carefully looked to; for if they have poor rooms and no bathing accommodations, they are naturally careless in their household duties. Servants should not sleep on the ground floor, especially near closets. Hard floors are an improvement; but there is too much upholstery in houses, and there should be fewer curtains, which retain the dust. The plumbing ought to be isolated as far as possible, and the New York Board of Health recommends a shaft for the purpose, running through the house. It is bad to have inside bath-rooms opening into sleeping-rooms. There must be an ample water supply, and he was glad that Ericsson's caloric engine is being used to pump water. There was special danger in sleeping in rooms opening into closets. Most soil-pipes were too large, and hence only partially filled by water. Dangers from sewer-gas are largely due to job-building, the employment of poor, cheap plumbers, and the ignorance of architects.

Prof. DOREMUS said that at the request of the President he had the honor to perform a few experiments, which would demonstrate how readily gas passes through porous media. He had been instructed in this by that distinguished man, the late Prof. John W. Draper, about forty years ago. In 1867, at his last interview with Prof. Liebig, that gentleman had said to him, "Don't leave Munich without visiting Voit and Pettenkofer's laboratory," and he saw there what he proceeded to demonstrate.

On the table was a block of brown sandstone, twelve by fifteen inches long, and four and three-fourths in thickness. On each side of this, a depression, a quarter of an inch in depth, had been made. Iron plates had been inserted in them, and attached by clamps. To each iron plate an iron tube was fixed. The whole surface of the stone, except that covered by the iron, had been coated with many layers of varnish. Prof. Doremus, by means of a flexible tube, connected the gas-pipe with the iron tube attached to the iron plate upon one side of the stone. After waiting a minute or two, he applied a lighted taper to the end of the other tube connecting with the sandstone on the other side, and a small flame sprang up, showing that the gas had passed through the solid stone. Prof. Doremus then took a block of brick-work, eight inches in thickness, made of Philadelphia brick, with plates and tubes attached in the same manner as to the sandstone. By blowing through one of the tubes, a candle-light, placed

at the end of the other, was deflected; and this deflection lasted for some time after the blowing had ceased, showing that it took some time for the air to go through the brick. Blowing still harder, the light was extinguished. Prof. Doremus added, that hydrogen or street-gas could be passed through stone in the same way, and that the pressure necessary to accomplish it was very small.

The next experiment was for the purpose of demonstrating the permeability of porous substances by gas, and the fourth experiment illustrated the fact that gas will pass through porous substances, notwithstanding it is opposed by the pressure of a whole atmosphere. What had been proven to be true of the gases used in the above experiments was true of sewer-gas and illuminating-gas. What steps, then, must be taken to protect ourselves from their evil influence? Water traps were inefficacious, for the gases would pass through the water and out into our houses. The only way was to kneel at the shrine of chemistry, and to make use of such substances as would decompose these poisonous gases. At Bellevue Hospital permanganate of potassium had been used for this purpose; Labarraque's solution, or the chloride of zinc, could also be used. Exposing the water and gas in our sewers to such agents destroyed all poisonous germs. Every emanation from our bodies, with few exceptions, is a compound of hydrogen, and there is not one of them that cannot be destroyed by chlorine, bromine, or some such substance.

Suppose a case of scarlet fever occurring and resulting in the impregnation of the walls of the house with the poison. Bromine or chlorine, both of which readily volatilize, may be used to destroy the poisonous germs. In 1865, the ship "Atlanta" arrived in New York with a number of cholera patients on board. Sixty of her passengers had already died. The "Atlanta" and all other vessels entering the Narrows were treated with chlorine, bromine, and other similar agents, and with the result of stamping out the disease entirely.

Dr. Agnew had informed the speaker that about thirty years ago the north wing of the old New York Hospital became so foul from the reception of a large number of ship-fever patients as to be unfit for use. Ventilation was tried, but in vain. Three workmen, engaged in scraping the walls, sickened and died. At the Lincoln County Hospital, England, the walls became magazines of disease in the same way. They were gutted and replastered, but doing no good, they were torn down to the very foundation. Some years ago certain surgical wards in Bellevue Hospital became so infected that many patients died of pyæmia. At the request of the Commissioners of Charity and Correction, Prof. Doremus attempted to purify them by the use of chlorine gas. The enormous amount of three tons of this gas was generated in these wards, and though many weeks were necessary for its accomplishment, the result was very satisfactory. Dr. James R. Wood had stated that since then no cases of pyæmia had occurred. Every few months now the chlorine treatment, though in a less rigorous form, is resorted to. He thought he was warranted in saying that, owing to the porous character of all walls and the decomposing power of certain gases, we can purify the most stately edifice if we would adopt the heroic chemical treatment.

Prof. Doremus said he spoke upon this occasion with a good deal of feeling and earnestness. On the first of last December he was to have delivered a lecture, illustrated by experiments, in which his son, fourteen years old, was to have assisted. The day before that son died from the evil effects of sewer-gas. Another son was just now recovering from the effects of an illness due to the same cause. He would have rather given his son the deadliest poison in his laboratory, and have trusted to the antidotes, than to have had him inhale this sewer-gas, for the deadly effects of which we have no remedy.

Dr. WILLARD PARKER said we had all known, he thought, of the fearful destruction of life in the wards of certain hospitals after they had become old and the walls saturated with disease. We had supposed fumigation and white-washing would remove the cause of disease, but had now been informed that this kind of treatment was of little or no avail. He would never forget the condition of things in Bellevue Hospital in 1846, when its wards contained so many patients with ship fever. He had never seen any disease which he really dreaded except ship fever. At the time referred to the wards were filled to their utmost, and Dr. Riess was house physician. Going through the wards in the morning they would pick up a dozen or more that had died during the night. It was supposed that the patients were crowded too much. Beds were laid upon the floor, but the death-rate continued very large. The subject then came up before the Medical Board, and it was decided that, as no more patients could be accommodated in the wards of the hospital, tents should be erected in the yard under the trees. The result was that nearly all the patients placed in tents recovered.

Many of those present may remember the vessel "Phœbe," which was driven upon the shore at Perth Amboy in 1847. Many patients with typhus fever were on board. A large number of deaths had already occurred; but when the ship went ashore and the patients were taken out and placed upon the ground, under the trees, and in hastily improvised canvas tents, or stalls, not one of the eighty-four thus placed died. These instances only showed the great importance of having the right kind of air to breathe.

Previous to the introduction of Croton water into New York in 1846, he did not remember of having seen a case of diphtheria. We had cases of croup, or membranous croup, as it was then called. Occasionally we met with a case of sore throat which was diphtheritic in character, the tonsils being enlarged and covered with a little whitish membrane. Diphtheria was the result of sewer malaria. There were none of us who had been in practice many years but could recall instances where the disease had occurred in families and swept away several members, and apparently without any cause. "Suppose, sir, Mr. President," the speaker asked, "there was a vault containing dead bodies near your house, would you be willing to have a tube connecting your bed-room with it?" Yet this is practically what we do with our sewers. I say, sir, that whenever diphtheria occurs there is something wrong with sewerage. Now, if I were going to build a house, I would not have it connected in any way with the sewer. I would have old-fashioned bowls and pitchers upon my washstands. Back of the house I would have constructed a sort of annex, where I should have all the sewers, closets, and all the pipes of the house. This matter demands our most earnest attention. New York, in this respect, is in a very critical and unhealthy condition, and the time has arrived for energetic action.

The PRESIDENT then referred to the presence of two physicians who had been members of the Board of Health, and said he would call upon them in the order of their seniority.

Dr. VANDERPOEL, one of the Honorary Fellows of the Academy, remarked that one thing was certain, the time had now come when physicians should know not only the principles of their profession, and two or three of the natural sciences, but they must know the elements of plumbing, and the sanitary construction of houses, so as to point out their defects, as it was impossible to trust mere mechanics. One defect not

pointed out in the paper of the evening is, that there is no soil drainage proper in New York. Though there are sewers connecting with every house, there is no chance for the moisture of the soil to escape. Phthisis has been shown here and in England to be induced by this character of the soil. In England the use of a proper system of drainage has reduced the disease. There is much filled soil here, and no provision has been made for the release of the water contained in it. While it was desirable to have soil-pipes exposed to view, it was practically impossible, as they would disfigure elegant dwellings, and in small houses space was too valuable. All joints of pipes should be carefully caulked with tow, lead, and sulphur. But when the pipe is set in a slit in the wall, the caulker could reach only half way round it, and the rest of the distance about the joint was untouched. The sanitary engineer was assuming an important place in the professions, and every house should be inspected.

Dr. JANEWAY said it was hard to distinguish between sickness from sewer-gas and sickness due to disease-germs entering sewer-pipes. Small-pox may come from germs in the sewer, but no one would attribute it to sewer-gas. Excluding diphtheria, he thought all would agree that contagious diseases did not arise from sewer-gas.

The portability of the germs of diphtheritic disease was much greater than was generally supposed. He knew of a case very recently where a child was taken sick with diphtheria in the country. Its clothes were brought home, and three members of the family sickened of diphtheria. We should correct the defects in our sewers, but we should not lose sight of a more important point, the portability of contagious germs. In his own practice it had occurred that diphtheritic germs were carried from Brooklyn to Florida in a trunk. Another point not to be lost sight of, is the possibility that much of the typhoid fever does not come from breathing sewer-gas, but from drinking water containing the germs of the disease, which have been drawn up into the water-pipes, and in that way get into the alimentary canal. In a case under his observation, several children were sick in a large house. He turned the water on below, and then turning it on above, the air was sucked into the pipes below. These faucets were over some drain-pipes connecting with closets, where diphtheritic stools had been deposited, and the water above, which was subsequently drunk, was thus tainted. This occurs also where there is no trap, or where there is no direct communication with the sewer. Dr. Janeway closed by explaining some tests with the chlorate of lithium.

Dr. PETERS was called upon by the Chair, and spoke of the large amount of sickness caused by foul docks. He recommended the carrying of sewer-pipes out to the end of docks.

The PRESIDENT then presented the prospectus of a plan for instructing the general public, policemen, firemen, etc., in the general principles of nursing.

Dr. AUSTIN FLINT, Sr., proposed resolutions approving the plan, which were adopted.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, February 2, 1882.

E. L. DUER, M.D., PRESIDENT, IN THE CHAIR.

Sponge-Tents.—Dr. ALBERT H. SMITH said it is not necessary to dilate upon the necessity of mechanical dilators for the neck of the uterus, both as a means of diagnosis and as an important therapeutic measure. The original sponge-tents were made from a flat piece of sponge, saturated with wax, and pressed flat between pieces of marble. This form of tent is comparatively useless, as it expands in one direction only. The first suggestion of the present form was, I think, by Dr. Sims in his work on *Uterine Surgery*. His method consisted in immersing a conical piece of sponge in a strong mucilage of gum-arabic, impaling it upon a wire skewer, and winding it tightly with a cord, after which it was hung up to dry, when the cord and skewer were withdrawn, and the tent smoothed with sandpaper. If the cord was wound on the sponge with sufficient tightness to give the tent useful expanding power, great difficulty was experienced in withdrawing the stylet. I was led to make a few changes in the method, and now employ a cylindrical piece of sponge, which is saturated with water only, and, without any stylet, is wound with a piece of fishing-line, to which a six-pound weight is attached; this compresses it thoroughly, and its form is easily given by the fingers during the process of rolling. The surface should be made as smooth as possible by means of sandpaper. The tent should be of uniform size from end to end. If it is conical, the tent is introduced as far as possible, but only the small part, without much dilating power, enters the internal os, and it is not unfrequently withdrawn unexpanded, while the external os and the cavity of the cervix are widely dilated. The sponge selected should be strong and fine. I have seen tents made from coarse, rotten material, which would break during the extraction, leaving portions within the cavity of the uterus.

The introduction of medicating materials into an internal cavity of the tent is objectionable, as they usually corrode the sponge, and the space and loose winding necessary to allow the removal of the stylet reduce materially the dilating power. The curved shape is useless, as the uterus can be straightened before the insertion of the tent, and less force is needed for the insertion of a straight one.

To prepare the uterus for the introduction of a tent, first use a dilator of soft metal, or a graduated wax bougie, to straighten the cervix and measure the length and calibre of the uterine cavity, noting tortuosities, etc.; then rapidly introduce the largest tent possible, having first coated it with an enamelling material—as soap—and immersed it in a box of salicylic acid in fine powder, which is to be rubbed in thoroughly to form an antiseptic paste over the tent. A sponge-tent thus prepared may be allowed to remain in situ for forty-eight hours without developing any unpleasant odor, unless there is breaking-down tissue, which may overpower the disinfecting powers of the acid. For ease in inserting, I have had constructed a peculiar, powerful forceps to hold the tent, which is clamped tightly, and enables the operator to pass it rapidly to its position. Hot-water injections after the tent is in position will expand the sponge rapidly, and fix it in about a minute. If pain follows the insertion, it can be controlled by opium suppositories.

If the tent is removed at the end of twenty-four hours, it will cause hæmorrhage, because the spongioles have buried themselves into the cervical tissues, which grasp it tightly, and a forcible extraction will drag away portions of the uterine tissue, and leave a raw and absorbing surface. But at the end of forty-eight hours the tent comes away easily without any bleeding. The contractile power of the uterus still remains at the end of twenty-four hours, and the presence of a finger or application in the cavity of the uterus causes rapid contraction. At the end of forty-eight hours the uterus is paralyzed, all pain has ceased, and local irritability is less. When the tent is removed, wash out the cavity of the uterus with tepid, salicylated water, and, if necessary, introduce a second tent.

Among the advantages of the sponge-tent are its slowness of dilatation—not slowness of expansibility. The power of the laminaria-tent is greater as a dilator,

but it will slip from the uterus as soon as it has ceased expanding, while the sponge-tent will remain as long as it is wanted. The sponge has also a disintegrating power over morbid surfaces. The healthy tissue will contract again, but diseased structures will not contract, but will slough off, their vitality being destroyed. The sponge being porous, discharges will pass through it.

The usefulness of the sponge-tent is for both exploratory and therapeutic purposes. It causes less pain than the laminaria-tent, and after its removal there is less tendency to contraction, and it is, therefore, more satisfactory for exploratory preparation. The sponge has a stimulant effect on the uterine parenchyma, and in cases of chronic metritis and hyperplastic enlargement it will cause a reduction of bulk. In one case, after the prolonged use of internal applications of iodine, nitric acid, etc., the repeated use of sponge-tents resulted in a complete restoration of the uterus to the natural size. In cases of stenosis the laminaria-tent may be preferable, and I prefer it to cutting operations or the use of powerful steel dilators. In one case, years ago, I introduced a sponge-tent in my office, and allowed the woman to walk home, and keep about her daily duties. The menstrual flow came on two days later entirely without pain, for the first time in the patient's experience; the flow escaped through the sponge and the latter was then removed. Conception occurred before the next menstrual period. The sponge-tent is also the safest agent for the destruction of granular growths of the endometrium. A patient had been bleeding profusely at every period for three years; supposing a polypus to be the cause, a sponge-tent was introduced to secure dilatation; a finger was introduced into the uterus, but finding no polypus, more tents were passed to the fundus, and fungoid growths of the endometrium were broken up by the tents. I was disappointed in my expectations of finding and removing the supposed cause of the hæmorrhages, but was agreeably surprised to find the patient remain well after the uterus contracted. Another patient was sent to me from Boston, for diagnosis only. I obtained permission to use a tent for exploratory purposes. I dilated the uterus with the largest sponge-tent passed to the fundus, introduced my finger and found fungosities on the anterior wall, but the means intended for exploration resulted in a cure.

In a case of polypoid pedicellated growths, I at once dilated with sponge-tents after the use of the wax bougie. The finger found a pedicellated growth as large as a hen's egg, but the tent had disintegrated it, and it could be removed by the finger without instrumental aid.

(To be continued.)

CORRESPONDENCE.

ABORTIVE TREATMENT OF FELON WITH COPAL VARNISH.

To the Editor of THE MEDICAL NEWS:

THE MEDICAL NEWS of January 28 contains an article upon "The Abortive Treatment of Felon with Copal Varnish," by A. B. Isham, M.D., of Cincinnati, O., in which the writer attributes the abortive influence to turpentine and pressure. As confirmatory of the views there expressed, I will state that the negroes of the pineland region of South Carolina very commonly treat whitlows with the "dip" taken from the box in which the crude turpentine, or gum, is collected, containing the rosin and turpentine in a state of union. They are separated by "stilling," or distillation. The affected finger is smeared with the "dip" taken from the tree-box, and wrapped up closely in a piece of cotton or linen cloth. A domestic remedy, used by the whites, is to dip the finger threatened with felon in boiling turpentine, the turpentine boiling at a much lower temperature than water. Both of these methods are fairly successful, but neither are specifics. Another domestic remedy is dipping the finger in water as hot as can be borne. I suppose both of these hot applications are efficacious from the well-known astringent action upon the capillaries that hot fluids exercise. The writer, I presume, is familiar with the practice of applying lunar caustic over the skin of the affected finger, although he does not mention it. This will occasionally prove abortive. I presume all of these remedies, although widely different in character, act somewhat in the same way, abating inflammatory action by their constrictive action on the capillaries of the part.

Yours very truly,

BENJAMIN RHETT, M.D.

SUMMERVILLE, S. C., Feb. 1, 1882.

NEWS ITEMS.

BROOKLYN.

(From our Special Correspondent.)

AMONG the changes in the departments incident to the new *régime*, we note that Dr. Jas. Crane has been succeeded by Dr. Jos. H. Raymond as the Commissioner of Health.

Steps are being taken to organize a night medical service under a law passed in 1881. Five thousand dollars will be set aside for that purpose when the Board of Apportionment meets.

CANADA.

(From our Special Correspondent.)

CANADIAN VETERINARY COLLEGES.—The attendance at the Toronto and Montreal schools this season is large, over one hunded students at the former and about fifty at the latter. In both the majority of the students are Americans, even the most distant States, as Texas, sending representatives. The Montreal school is affiliated with the medical faculty of McGill University, and the pupils take botany, chemistry, and physiology with the medical students. The course extends over three years, six months' session, with matriculation, primary, and final examinations.

HOW TO GET RID OF A PROFESSOR.—The difficult question of how to get rid of an unpopular or inefficient professor was recently solved in a Nova Scotian college by the students "striking" in a body, and refusing to attend his lectures.

MEMORIAL TO DR. ROLPH.—It is proposed to erect a memorial to the memory of the Hon. Dr. Rolph, who for many years was a prominent medical man and politician in Ontario. He founded the Victoria Medical School in Toronto, better known as Rolph's School, which did not long survive his death, in 1869.

EFFECTS OF FEEDING A CALF WITH TÆNIA.—In connection with the course of lectures on helminthology at the Montreal Veterinary College, the interesting experiment was recently made of feeding a calf with ripe segments of tænia saguiata. The animal became ill, and when killed, seven weeks later, there was well-marked cestode tuberculosis, the muscles swarming with the larvæ or cysticerci.

HEALTH IN MICHIGAN.—For the week ending Feb. 4, 1882, the reports of the Michigan State Board of Health indicate that influenza, scarlet fever, and ton-

sillitis have considerably increased, and that rheumatism and pneumonia have considerably decreased in area of prevalence.

Reports have been received showing small-pox present during the week ending Feb. 4, and since, at thirteen places in Michigan, as follows: On a vessel at St. Joseph, Berrien Co. (1 case), Feb. 2; in Park Township, St. Joseph Co., Feb. 2; in Spalding, Menominee Co. (14 new cases), Feb. 3; in Elkland Township, Tuscola Co. (1 case), Feb. 3; at Kalamazoo, Grand Rapids, Saginaw City, Detroit (2 new cases), and Marshall (1 case), Feb. 4; in Port Huron Township (8 cases), Feb. 5; in White Cloud, Newaygo Co. (3 cases), near Menominee (1 case), Feb. 6; in Kimball Township, St. Clair Co. (4 cases), Feb. 7, 1882.

Other contagious diseases are reported at places too numerous to mention; scarlet fever at twelve places, diphtheria by twenty observers, at eighteen places.

FIRES IN THEATRES.—In the *Revue Scientifique*, January 7, 1882, there is an interesting historical and statistical review of the different disasters which have occurred in places of amusement from fire. At its conclusion, the author alludes to the experiments of M. Monnier, on the chemistry and physics of the gases produced in combustion, and gives the recommendations of M. Karl Vogt, based on these studies, as to the means by which suffocation can be best avoided under such circumstances. These are: 1. The replacing of the drop-curtain by a metallic screen, which will completely shut off the auditorium from the stage, and which must be capable of being placed in position with the greatest ease and despatch; and 2. The placing in the ceiling of the stage, and above the chandelier, of a large ventilator, which can be readily opened, and by which the deleterious gases, greatly expanded by the heat, may be allowed to escape, and access to the firemen thereby rendered safe.

The *Lancet*, January 7, in a short article on the "Anatomy of Panic," recommends that "the managers and chief performers should make it a point of honor to keep *their* self-possession, and preserve smiling faces above the footlights if any hitch occurs."

In addition to these, it would be well if the public were accustomed to the use of all the means of exit, and all exit doors should only be fastened on the inside, and by bolts which can be readily slipped. All passages to exit doors should be so labelled, and the law should require them to be kept unobstructed.

INTERNATIONAL HYGIENIC CONGRESS.—The fourth annual session of the International Hygienic Congress will be held at Geneva, Switzerland, from the 4th to the 9th of September, 1882. An exposition of publications, plans, designs, and objects of all characters relating to hygiene, will be held in Geneva from the 1st to the 30th of September.

SURGEON-GENERAL BARNES.—A press despatch from Washington states that Surgeon-General Barnes is not to be retired for the present, owing to the fact that a bill is pending in Congress to provide for his retirement with the advanced rank of Major-General, in recognition of his services in connection with the illness of President Garfield. It is eminently proper that such recognition should be made, and its fitness has already been urged in these columns.

THE ILLUSTRATED QUARTERLY OF MEDICINE AND SURGERY.—The prospectus of the new journal, whose début we announced a fortnight ago, is issued. Each number will consist of four quarto plates, with twenty-four pages of text. It will only contain original matter, and will be under the able editorial management of Drs. George Henry Fox and Frederic R. Sturgis, which should assure to it the success which we trust it may attain.

SMALL-POX.—The returns for the week ending February 11 show a mortality in New York of 21; in Philadelphia, of 15; Pittsburgh, of 27; Boston, of 1; Titusville, Pa., of 1; Cincinnati, of 25; Chicago, of 20.

PARIS FACULTY.—Prof. HAYEM has been transferred from the Chair of Therapeutics to that of Pathological Anatomy, vacant by the nomination of M. Charcot to the new Chair of Nervous Disease.

UNIVERSITY OF THE CITY OF NEW YORK.—Dr. Wm. C. Jarvis has been appointed Lecturer on Laryngology, vice Prof. J. Elsberg, M.D., resigned.

PERSONAL.—The busts of Dupuytren and Baron Larrey have just been placed in the gallery of the French Institute.

OBITUARY.

SIR ROBERT CHRISTISON, BART.

THIS illustrious physician and toxicologist died on the morning of the 27th of January, at his residence in Edinburgh. He attained the unusual age of eighty-five years, having been born in 1797. If we except the severe illness which led to his retirement from active life in 1877, and from which he afterwards almost completely recovered, he enjoyed comparatively good health until a month ago, when he was laid up with a severe catarrh, from which he never rallied. He was the son of Prof. Christison, who for some years occupied the Chair of Humanity in the University of Edinburgh.

He commenced his university studies in the year 1811, passing through both the arts and medical curriculum. Graduating after eight years, and having had the advantage of being for two and a half years resident physician at the Royal Infirmary in his native city, Dr. Christison proceeded to London and Paris. At the latter place he studied under M. Orfila, the celebrated toxicologist, and soon became a specialist in that department of medical science.

Shortly after his return to Edinburgh, and at the early age of twenty-five, he was appointed to succeed Alison as Professor of Medical Jurisprudence in his *Alma Mater*, in which position he remained for ten years. During this period he published his widely-known *Treatise on Poisons*, a toxicological work which for completeness, scientific accuracy, and philosophic spirit has never been equalled in any language. Although it is now more than fifty years since its first publication, it still remains the standard work on the poisons of which it treats.

On the death of Duncan, in 1832, Dr. Christison was transferred to the Chair of Materia Medica, which position he occupied until 1877, when failing health compelled him to resign, his successor being his former assistant, and the well-known pharmacologist, Dr. Thomas R. Fraser.

Prof. Christison's lectures formed for many years one of the chief attractions of the Edinburgh Medical School; and this is no meagre praise when it is remembered that among his colleagues were such world-famed surgeons and physicians as Syme, Simpson, and Gregory. His popularity as a lecturer continued to the end, and none were more venerated and loved by his pupils, who are now to be met with in every part of the globe, than Sir Robert Christison. Exact in his information, lucid in exposition, lively and almost playful in manner, occasionally illustrating his subject with an appropriate anecdote, most generous and sympa-

thetic in his relations to his students, his lectures were listened to with genuine pleasure and appreciation.

In his extra-academical life he was no less fortunate. He was for many years the most popular consulting physician in Scotland; and he was appointed physician in ordinary to the Queen for Scotland. His services as a toxicological expert were in much request throughout Britain, and in this capacity his name is associated with all the notable poisoning cases of the last half century.

Besides the *Treatise on Poisons*, to which we have already alluded, he wrote the article "Poison" for the seventh edition of the *Encyclopædia Britannica*, and the article "Orfila" for the eighth edition; not to speak of numerous papers, elsewhere published, on the toxicological effects of arsenic, opium, and other drugs. He has also rendered valuable service to the profession in connection with the last edition of the *Edinburgh Pharmacopœia*, merged, since 1864, like those of London and Dublin, in the *Pharmacopœia Britannica*, prepared under the auspices of the General Medical Council. In his *Dispensatory*, published in 1842, he presented a commentary on the then existing pharmacopœias, characterized, like his book on poisons, by precision in detail, and by the concise, yet happy, expression of suggestive generalizations. He has also contributed some valuable clinical and pathological memoirs. His work on the *Granular Degeneration of the Kidneys*, written in 1838, is still held in high estimation.

Another form of disease to which he devoted special attention was that of fever, in its numerous and perplexing varieties. In this case he was able to speak from personal experience, for, owing to a peculiarity of constitution, he was liable to suffer frequently from tolerably severe febrile attacks. He gave the results of a long clinical experience in a paper on the "Changes which have taken place in the constitution of Fevers and Inflammations in Edinburgh during the last forty years." He held that fever had changed from sthenic to an asthenic type, and that, whereas venesection was at one time servicable, it was now injurious. It was not a mere change in the manner of our therapeutics.

Dr. Christison also did much to improve and cheapen the dietary of Scotch prisons, and other public institutions, by his elaborate investigations in the effects on the health of the prisoners of various forms and combinations of food.

Throughout his long and brilliant career he received many public tokens of the esteem in which he was held by all. In 1866, the University of Oxford bestowed on him the highly honorary degree of D.C.L., and, in 1872, his own University made him, while yet a professor within its walls, an LL.D., an honor without precedent in its annals. He was twice elected President of the Royal College of Physicians of Edinburgh, and he was for some time President of the Edinburgh Royal Society. He was offered the Presidency of the British Medical Association in 1875, but he was obliged to decline the honor on account of infirm health. In 1871 he was made a baronet by the Queen, in recognition of his position as premier physician of Scotland. He was professor for the very long period of fifty-four years, a length of service unequalled in the records of the University since its foundation.

In 1872 the jubilee of his professorship was celebrated with great *éclat*. The University Volunteer Company, of which he was captain, presented him with a sword of honor; the Edinburgh University Club, of London, which is presided over by the Duke of Argyle, sent him a congratulatory address, and a banquet was given in his honor, at which were present many of the most eminent literary and scientific men in the kingdom.

In person he was tall and broadly, though not stately, built; even to the last he walked remarkably erect, and the litheness of his step often excited astonishment. Only a few months before his death he had ascended one of the highest of the Scottish hills, Ben Nevis, and this was no uncommon feat during the last decade of his life. The baronetcy falls to his eldest son, Alexander Christison, who is Deputy Surgeon-General of the Bengal army and Principal of the Agra Medical School.

NOTES AND QUERIES.

THE POTASH THEORY OF URÆMIA.

To the Editor of THE MEDICAL NEWS:

SIR: In glancing over your issue of January 7, I noticed a clipping from the *Bull. Gen. de Therap.*, of September 15, 1881, on a new theory of uræmia by MM. Feltz and Ritter, saying that a "certain quantity of the salts of potassium contained in the blood influenced in a certain degree the amount of urea necessary to produce grave or fatal results." I do not know whether I would have paid any special attention to the paragraph had it not been for the following circumstances: During the prevalence of scarlatina in our village I was over-solicitous for the welfare of my youngest daughter, a bright little thing of four years, she having at the time an *infantile eruption* of the lower extremities. I gave her three times a day chlo- and iodide of potash regularly, in order to relieve her of the sores, but more especially to charge her system with potash to lessen the severity of the attack of scarlet fever, as I supposed. Now she was the *only case in the village that died of uræmic poison*, and, in fact, the only one who succumbed to the disease in thirty or forty cases. I just give you this one instance; whether there was anything in it, or only a coincidence, I cannot say.

Very respectfully yours,

L. M. SENCINDIVER, M.D.

DARKESVILLE, W. V., January 25, 1882.

[Our correspondent's case is a striking clinical confirmation of the potash-salts theory of uræmia. Since the publication of Feltz and Ritter's experiments, Astaschewsky, of St. Petersburg, has announced that he had arrived at the same conclusion. He found no effect from the injection into the blood of urea, or creatinin, but the mineral constituents of the urine caused uræmia. When the potash salts were removed from them, no effect was produced. It seems to be established, therefore, that the retention of the potash salts is the cause of uræmia. The practical applications of this fact are obvious.—ED.]

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 7, TO FEBRUARY 13, 1882.

CAMPBELL, JOHN, *Lieutenant Colonel and Surgeon.*—Medical Director Department of the South. Granted leave of absence for fifteen days from 13th inst.—*S. O. 17, Department of the South, February 11, 1882.*

GARDNER, WM. H., *Captain and Assistant Surgeon.*—Assigned to duty as Post Surgeon at Fort Concho, Texas.—*S. O. 13, Department of Texas, February 6, 1882.*

TREMAINE, W. S., *Captain and Assistant Surgeon.*—Who reported at these headquarters January 9, 1882, per par. 12, S. O. C. S., A. G. O., will await further orders in New York City, from date of his so reporting.—*S. O. 20, Department of the East, February 7, 1882.*

BARTHOLF, JOHN H., *Captain and Assistant Surgeon.*—Fort Lapwai, Idaho. Granted leave of absence for fifteen days.—*S. O. 12, Department of the Columbia, January 25, 1882.*

WOOD, M. W., *Captain and Assistant Surgeon.*—The seven days' leave granted him on 4th inst. by Post Commander Fort Brady, Mich., is extended twenty-three days.—*S. O. 19, Department of the East, February 6, 1882.*

COMEGYS, E. T., *Captain and Assistant Surgeon.*—To be relieved from temporary duty at Columbus Barracks, Ohio, on receipt of order, and to report in person to Commanding General Department of the Missouri for assignment to duty.—*S. O. 32, A. G. O. February 9, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

ON PRIAPISM ACCOMPANYING INJURIES OF THE SPINE.

An Abstract of a Clinical Lecture Delivered at the Pennsylvania Hospital, February 11, 1882.

BY WILLIAM HUNT, M.D.,
SURGEON TO THE HOSPITAL.

GENTLEMEN: In the *Medical News and Abstract* for November, 1881, I discussed in a lecture on Injuries of the Spine, the symptom of priapism which sometimes exists after those injuries, and which, when it does occur, is a sure index of what has happened, and mostly is of very serious import. I also called attention to the fact that it may exist after injuries anywhere along the column, and that I could confirm this from my own clinical experience. I then showed that the explanation is not to be sought for on the theory of centres somewhere in the cerebro-spinal axis, but that the phenomenon is due to disturbance of the vaso-motor nerves, through the direct involvement of the sympathetic and its ganglia in the injury. I also called attention to the fact that in normal erection the intensity of sexual passion, or local irritation overcomes the inhibitory function of the sympathetic system, and that this function is also overcome when the sympathetic is lacerated, irritated, or divided at the same time that the cord is injured, in the latter case erection occurring without sensation, and being more or less persistent according to the severity of the injury.

"Thus," I say, "it is not necessary to trouble one's self about a special nerve-centre ruling over the function we are considering. Thus also this symptom in accidents to the column and cord is explained; also why some have it and others do not, why it is evanescent in some and in others almost constant, why it may appear in injuries occurring anywhere along the spine, why there is no sensation when it occurs as an accompaniment of laceration or pressure on the cord, for communication with the brain is cut off, and why, also, it is rare to find it in disease of the membranes or cord.

"When the wounding missile or crushing force breaks the spine and involves the cord, and there is accompanying priapism, then the neighboring ganglia or nerves of the sympathetic are bruised or wounded at the same time, from being caught in the line of the crush or wounding missile. When this symptom does not occur, the sympathetic has escaped. I have no doubt that when it occurs in hanging, the superior cervical ganglia of the nerve are caught in the squeeze. In most cases of disease the lesion is within the canal, and the sympathetic fibres or ganglia are not involved."

This explanation has not been accepted by some of my physiological friends as entirely satisfactory, but their views are based mostly upon theoretical grounds.

A most interesting case has just come under my care, and appears to me to give great force to the views expressed. The following is the clinical history:

Thomas McC——, stevedore, aged fifty, was brought into the Pennsylvania Hospital February 1, 1882, about 10 o'clock, A. M. A short time before, he fell through the hatchway of a vessel upon the shaft alley, a distance of about ten feet below, and struck with great force upon the back of his head and neck. He was a large and splendidly muscular man, with no superfluous fat. He was perfectly conscious, but absolutely paralyzed, both as to sensation and motion, from the line of the second rib downwards. The skin was sensitive over the deltoids, but below this there was no feeling or power of motion in the upper extremity.

He complained of no pain, but had a terrible sense of constriction, and a feeling of want of breath. The breathing was entirely diaphragmatic. The thoracic muscles could not be seen in action anywhere. There was priapism, which, for most of the time, was complete, and always marked. The pupils were contracted and irresponsive to light. Electro-muscular contractility was not impaired. There was scrotal and plantar reflex after recovery from shock; the temperature in the axilla rapidly rose from 97° to 105°, which point it reached on the fourth day, when the patient died. The respirations ranged from 20 on the first day to 32 on the last. On this day they were very labored, as was indicated by the movements of the larynx. The chest was greatly expanded, and there was a deep sulcus across the superior abdominal regions; below this there was meteorism. The pulse-range was from 50 on the first day to 98 on the last, and always feeble. The urine was drawn off with a catheter; it was of 1035 sp. gr., and loaded with phosphates. The surface temperature was, on the second day: Scrotum, 97⅘°; inside thigh, 96°; third day, scrotum and thigh, 96⅘°; fourth day, inside thigh, 98½°. The dyspnœa increased, and the patient became unconscious before death. The diagnosis was based on the symptoms only, for it was not deemed prudent to raise the patient from his bed or to turn him. It was diagnosticated that there was a fracture of the cervical vertebra from the third to the fifth, with laceration of the cord, but not completely involving the phrenic nerves, for by these alone the patient breathed. The opinion was ventured, also, that the cervical portion of the sympathetic nerve was involved in the injury.

Autopsy.—The chest and abdomen were first opened. The lungs were somewhat adherent from old pleurisy, but they were engorged with blood. The right heart was enormously distended. The neck was now carefully dissected. On raising the great vessels, a line of clotted blood from laceration laid along the deep muscles. The superior cervical ganglion of the sympathetic on the right side was carefully sought for above the injury. It was apparently intact, but upon tracing the nerve downwards, it *passed into a line of clot, and the third cervical ganglion was imbedded in a mass of blood, and a firm clot was pressing upon it.* The left side showed, also, blood clot in the same position, but the nerve was not dissected. Dr. Morris Longstreth, who was present and assisted at the autopsy, has carefully preserved the specimen. The clots about the nerve had nothing to do with the lesions of the column and cord which were now sought for.

In fact, the absence of hæmorrhage about the injuries which were here found was a matter noticed by all who were present. There was a complete and clean fracture through the intervertebral substance between the third and fourth cervical vertebræ, involving the bodies of both as though the bones had been subjected to rough grinding. There was also separation between the fourth and fifth and fifth and sixth vertebræ. Directly opposite the main lesions, those of the third and fourth vertebræ, the cord was lacerated and a small hæmorrhage had taken place within it. The patient

appeared to have sustained a tremendous blow with doubling backwards on the line of the main injury, while the other vertebral connections and the surrounding structures were stretched and lacerated.

Dr. Morris Longstreth made some thin sections of the superior cervical ganglion. Hæmorrhage into its substance is very distinct under the microscope. The inferior ganglion was subjected to grosser lesions, for hæmorrhages in and about it are visible to the naked eye. It is the intention of the Doctor to examine and report upon these lesions more fully.

Besides Dr. Longstreth, Dr. John H. Packard, Dr. Jos. M. Fox, the resident physicians of the hospital, and several other medical gentlemen, were present at the autopsy.

In this case do not the enormously distended heart, the engorged lungs, the temperature record, and the priapism, all point to involvement of the vaso-motor system in the injury, and consequent interference with its inhibitory or regulating functions?

The most skilful vivisectionist could not have made a cleaner and more limited break of the spine and laceration of the cord than were done by the accident in this case. There was no pressure on the cord from without by bone fragments or hæmorrhage. The cervical nerves arising above the lesion gave to the phrenics their partial power, and through them and the diaphragm the man lived by actually working for his breath. He *never slept!* Towards the last coma came on rapidly followed by death.

The unimpaired electro-muscular contractility was due, I take it, to the fact of the muscles being perfectly sound in structure and the response was *sui generis* and independent of nerve supply, for in these cases, when the patient lives long enough and the muscles become altered by degenerations, there is little or no response to the electric current. Patellar and ankle reflex were absent, probably because the deep muscular nerves were irresponsive to the rough shock necessary to produce them; while surface reflex through the cord below the lesion was present and is readily understood.

These facts, together with the lesions of the sympathetic nerve and the consequent vaso-motor phenomena, make the case, it appears to me, one of the most interesting and instructive ones on record.

ORIGINAL ARTICLES.

A REPORT OF SOME CASES OF GLAUCOMA

IN WHICH AN IRIDECTOMY ON ONE EYE SEEMED TO PRECIPITATE AN ATTACK OF ACUTE GLAUCOMA IN THE OTHER.

BY C. R. AGNEW, M.D., AND D. WEBSTER, M.D.,
OF NEW YORK.

OUR remarks upon these cases will be brief, as the cases are more interesting and instructive in themselves than anything we can say about them.

That an operation for the relief of acute glaucoma in one eye may quickly be followed by an attack of the same disease in the other, is no new doctrine to the ophthalmic surgeon. Von Graefe, who first performed the operation of iridectomy for the cure of glaucoma, also first observed and described the complication of which we speak. In his experience, the fellow-eye was attacked within fourteen days after the operation on the first in about thirty per cent. of the cases in which the operation was done for primary inflammatory glaucoma. The cases here related will show that it sometimes occurs after an operation for chronic glaucoma, or for painful glaucoma absolutum. In fact, we do not think it safe to operate upon one eye for glaucoma of any kind without previously warning the patient that the second eye may be attacked within a few days, or even a few hours, after the operation. The patient invariably attributes the attack in the second eye to the operation upon the first, and, if not informed beforehand of the possibility of its occurrence, will be very likely to blame the surgeon for withholding his knowledge of such liability.

We think it is now very generally conceded that the attack of acute glaucoma excited in the fellow-eye, in such cases, is not a true sympathetic inflammation. It is believed rather that anxiety of mind, the excitement attendant upon an operation, the hyperæmia of the eyeball, caused by the administration of ether, and the shutting up of the eye with a bandage, are sufficient to awaken an acute attack in an eye already predisposed to glaucoma. And we think it is fair to infer that an eye which has shown no glaucomatous symptoms, subjective or objective, *is predisposed* to the disease if the fellow-eye is so affected.

In the majority of cases where the second eye is so attacked, we have found it necessary to operate upon it with as little delay as possible, and in all these cases we have obtained satisfactory final results. In some cases, however, it will yield to antiphlogistic treatment. We remember a case operated upon at the Manhattan Eye and Ear Hospital, but not reported here, where the attack in the fellow-eye passed off in a day or two, under the use of eserine, and did not return. In the ninth case here reported, the attack in the second eye passed off without an operation, under the use of opiates and iced cloths.

In all our later operations for glaucoma, we have left the fellow-eye unbandaged, and in none of the cases where we pursued this method, have any symptoms of irritation in the second eye shown themselves. We have not followed this method in a sufficient number of cases to base an opinion upon, but we hope to find that the immediate attack upon the second eye will always thus be avoided.

Our *first* case is that of a married woman, forty years old, who came to us with a history of chronic glaucoma, in November, 1872. She had then R. V. $= \frac{20}{30}$, L. V. $= \frac{20}{40}$. Hm. $\frac{1}{36}$ each. T + ? both. Ophth.: Vitreous hazy, retinal veins enlarged and pulsating, disk reddened, retina looking œdematous, and a commencing crescent of staphyloma posticum in both.

She was seen again in February following, when all the symptoms were improved, and she read $\frac{20}{20}$ with each eye with $+\frac{1}{18}$.

On February 20, however, we were sent for, and found the left eye in a condition of acute glaucoma, with sight reduced to perception of light. Ether was at once administered, and a broad, peripheral iridectomy done upwards by Dr. Agnew. On the evening of the next day the fellow-eye was found hard, red, and painful. The pupil was dilated and the vision reduced to perception of light. Iced cloths were applied and anodynes administered, but as the eye was no better the next morning we again gave ether, and Dr. Agnew performed an iridectomy on the second eye. From this time the recovery was good, and some months later the lady read fine print with each eye.

Our *second* case is that of a carpenter and builder, forty-eight years old, who gave the following striking history: About six months before consulting us he went to church one Sunday morning, seeing as well as ever, and was led out by his sister "stone blind." He could see a little by the time he got home. He does not remember having had any pain at the time. Since that time his left eye has become bloodshot and painful, with obscuration of vision about once a month, the vision remaining a little worse after each attack, until *now* it is reduced to perception of light. Eyeball hard, but not red or painful; pupil hazy, not dilated, but sluggish. Ophthalmoscope revealed only a slight reddish reflex from fundus, because of diffuse opacity of the vitreous and translucency of the cornea. R. V. = $\frac{20}{30}$: $\frac{20}{20}$ with + $\frac{1}{12}$.

October 26. Iridectomy by Dr. Agnew on left eye.

The next morning there was a slight dull pain in the right eye. Two days after the operation the right eye was red, pupil dilated, and vision reduced to counting fingers at four feet.

On the third day after the operation on the left eye, an examination having shown that the acute glaucoma in the right was growing worse in spite of treatment, we placed the patient again under ether, and Dr. Agnew performed an iridectomy upon the right eye. The recovery was smooth.

In March, 1875, five months after the operations, R. V. = $\frac{20}{20}$ with + $\frac{1}{18}$ c. ax. 10°, and visual field normal. L. V. = counts fingers in a small field.

Our *third* case is that of a female nurse, sixty-eight years of age, with painful glaucoma absolutum of right eye, and chronic glaucoma of left. L. V = $\frac{20}{60}$; no improvement with glasses. Visual field less than one-fourth its normal size. Tension normal, but glaucomatous excavation of disk.

January 12, 1874. Iridectomy upon right eye, by Dr. Agnew, for relief of pain.

January 14. The fellow-eye has been injected, lachrymose and somewhat painful since the morning following the operation. Anterior chamber shallow, tension increased, vision cloudy. Dr. Agnew now performed an iridectomy on the second eye, and both recovered kindly.

In March, 1878, more than four years after the operations, the patient returned, complaining that the use of the left eye, which had now vision $\frac{20}{20}$, produced pain in the blind right eye, which was then enucleated with entire relief to the patient.

Our *fourth* case is that of a carpenter, forty-eight years old, upon whose left eye iridectomy was performed by Dr. Agnew, for glaucoma simplex, on October 1, 1873. The same night he complained of sharp, shooting pains in the eye operated upon, which were relieved by a hypodermic injection.

On the *third* day after the operation, the *right* eye became red, painful, and lachrymose, and vision was reduced from $\frac{20}{40}$ to counting fingers at two feet. Two leeches were applied to the temple, and atropia and iced cloths used. More or less improvement resulted, and the eye was kept under observation, and treated according to indications until the *eighth* day after the operation on its fellow, when the sight being still reduced to ability to count fingers, it was thought best to perform an iridectomy upon it also, which was accordingly done by Dr. Agnew. Both eyes recovered well after this.

Our *fifth* case was that of a married woman, fifty-two years old, whose father had been blind for fifteen years with glaucoma absolutum. She had a history of chronic glaucoma extending back over several years, and latterly of acute exacerbations in the right eye.

R. V. = $\frac{20}{200}$: no impt. with gl.
L. V. = $\frac{20}{100}$: $\frac{20}{20}$ with + $\frac{1}{24}$.

Ophthalmoscope showed left fundus and media normal; right, dotted and diffuse opacity of the cornea, more dense towards the centre, and shading off towards the periphery. An iridectomy was done upon the right eye by Dr. Webster, June 27, 1877, in the afternoon. The next morning, on removing the bandage, the left eye was found to be slightly injected, the iris bulging forwards, the pupil slightly enlarged and sluggish, and the vision misty; iced cloths were applied.

In the evening, the left eye was found a little worse in every way, and beginning to be painful. Codeia was ordered to relieve the pain.

In the morning of the *second* day after the operation, the eye seemed to be better. In the evening the patient counted fingers with each eye by candle-light, but more distinctly with the operated eye than the other.

The next morning, the *third* after the operation, there was no pain in the eye, but as the sight remained very much blurred, and all the symptoms of acute glaucoma persisted, we made arrangements to operate in the afternoon.

When we went prepared to operate at 4 P.M., we found the lady suffering from the most intense pain in the second eye. This pain had come on suddenly, about an hour before, and the patient described the feeling as that of a sharp knife being constantly thrust around the back of the eyeball. She declared she would rather have the eye taken out than to submit to the excruciating pain an hour longer. Upon separating the lids a large quantity of hot tears burst forth, the eyeball was found intensely congested, and there were many ecchymotic spots in or beneath the ocular conjunctivus.

The cornea was so cloudy that it was with some difficulty that the dilated pupil could be seen; the hardness of the eyeball was very marked, and the vision was only perception of light.

An iridectomy was at once done, under ether, by Dr. Webster. Six weeks after the operations

R. V. = $\frac{20}{30}$ with + $\frac{1}{18}$ c. ax. 180°.
L. V. = $\frac{20}{20}$ with + $\frac{1}{18}$ c. ax. 180°.

She has had no recurrence of the disease, more than four years having elapsed since the iridectomies.

Our *sixth* case is that of a married woman, sixty-three years of age, the subject of goitre, with a history of chronic glaucoma of the left eye, with acute exacerbations.

R. V. = $\frac{20}{60}$: $\frac{20}{20}$ with + $\frac{1}{24}$. Field and ophthalmoscopic appearances normal.

L. V. = $\frac{20}{200}$; no improvement with glasses. Field contracted to a diameter of *one inch* at a distance of *one foot*. Pupil enlarged and fixed; tension +; ciliary veins engorged; shallow anterior chamber.

Ophthalmoscope showed slight diffuse corneal opacity, extensive cupping of disk, with exposure of cribriform fascia.

A drop of a four-grain solution of eserine was put into the left eye, which caused a twitching sensation in and about the eye.

The next day the patient reported that the eserine caused pain for an hour or two, but did not improve the sight, and as we found the condition of the eye the same, we placed her under ether and Dr. Agnew performed an iridectomy upon the eye.

When the eyes were opened on the morning of the *second* day after the operation, neuralgia over the right eye was just commencing. The pain increased in severity, and kept her awake all night, although she took a grain of codeia. In the morning of the *third* day, eyeball red, pupil dilated and fixed, anterior chamber shallow, tension increased, corneal haziness, vision of fingers at three feet.

An iridectomy was done upon the eye, at 2 P.M., by Dr. Agnew, after which the patient slowly recovered. Six weeks later:

R. V. = $\frac{20}{20}$ with + $\frac{1}{20}$c. ax. 180°c. — $\frac{1}{60}$c. ax. 90°.
L. V. = $\frac{20}{100}$; no improvement with glasses.

Our *seventh* case is that of a maiden lady, forty-five years old, who had suffered from weak eyes since measles at fifteen. For five years she had been subject to attacks of neuralgia of the head, occasionally shooting into the right eye. For the last three years the sight of the right had been impaired, but the patient believed she could read with it up to the day before we saw her. She had never tried it separately, however. The eye grew red and painful the day before she consulted us, and she was kept awake all night by the pain. When we first saw her the lids of her right eye were slightly swollen, the eyeball red and watery, the pupil dilated and fixed, the anterior chamber shallow, the tension increased.

R. V. = $\frac{1}{200}$: $\frac{20}{70}$ with + $\frac{1}{10}$; field contracted.
L. V. = $\frac{15}{200}$: $\frac{20}{30}$ with + $\frac{1}{7}$; field normal.

Ophthalmoscope showed in the left eye no lesion; in the right, a diffuse opacity of cornea, which interferes with examination; but a cupped disk, surrounded by a broad whitish ring, can be discerned.

The right eye being very painful, we dropped into it some of a four-grain solution of eserine. An hour and a half later the eye felt much better. The patient was furnished with some of the same solution to drop into the eye twice daily.

Two days later, the patient reported that the eserine so relieved the pain that she had slept well both nights, but the vision was unimproved.

The next day, as the pupil remained dilated and immovable, and the vision unimproved, the patient was placed under ether, and an iridectomy done upon the eye by Dr. Agnew. On the sixteenth day after the operation, it was noted that the eye had steadily improved, and that the sight had risen to $\frac{20}{30}$ with + $\frac{1}{9}$. Seven weeks after the operation, as the fellow-eye was red and irritable, atropia was dropped into it, and adhesions of the papillary border of the iris to the anterior capsule of the lens were discovered. Atropia was then used, *coup sur coup*. Two days later the adhesions had been broken up, and the eye was feeling comfortable. The atropia was stopped.

Ten days later, or at about the end of the ninth week after the operation on the first eye, the patient came to us with well-pronounced acute glaucoma in the other. The first eye was looking well. Ether was now given, and an iridectomy done upon the second eye by Dr. Agnew. Ten days later R. V. = $\frac{20}{30}$ with + $\frac{1}{9}$, L. V. $\frac{20}{70}$ with + $\frac{1}{8}$. The eyes gave no further trouble.

Our *eighth* case is that of a married woman, twenty-six years old, who one evening had pain in her right eye before going to bed. There was also some obscuration of vision, but the next morning the pain had passed off, and the sight seemed as good as ever.

Similar attacks occurred several times, when, becoming alarmed, she consulted an ophthalmic surgeon, who performed an iridectomy upwards upon the affected eye.

Inflammation, with loss of vision, set in on the *second* day, and on the *third* acute glaucoma attacked the fellow-eye. She presented herself at the Manhattan Eye and Ear Hospital one week later, when her condition was as follows:

Right eye red and painful; lens opaque and swollen; no anterior chamber; tension much increased; vision reduced to perception of light. Left eye red and painful; tension increased; very shallow anterior chamber; pupil so widely dilated that only a very narrow rim of iris could be seen, this rim being a little broader below than elsewhere. Opacity of the media prevented the fundus from being seen. Vision of fingers at nine feet.

Ether was given, and, Dr. Agnew operating, a circular disk of the right cornea was removed by means of Bowman's smaller trephine. A portion of the swollen lens matter escaped through the opening.

An iridectomy downwards was done on the left eye at the same sitting, and, in order to keep up the drainage from the eye for a longer period, a small piece of cornea was snipped away with the scissors at one extremity of the wound. Both eyes recovered kindly.

Eleven months later it was noted: Right pupil closed by a dense membrane, perception of light, but very imperfect projection.

L. V. = $\frac{20}{40}$ with + $\frac{1}{42}$s. c. + $\frac{1}{48}$c. ax. 180°. No cupping of optic disk.

The patient was examined two years later and the condition was found unchanged.

Our *ninth* and last case is that of a woman, forty-five years old, who, upon consulting us in September, 1876, stated that she had suffered from very severe pain over her right eye for six weeks. The pain had generally been worse at night, and had grown much worse in the last two weeks.

Eye red, vision of fingers at one foot, pupil widely dilated, anterior chamber shallow, tension increased.

Ophthalmoscope showed only a faint reflex from the fundus. L. V. = $\frac{20}{40}$; sufficient old corneal opacity to account for the lowering of vision.

September 8. Iridectomy upon right eye by Dr. Webster; slight hæmorrhage into pupil. No atropia used.

The next morning the blood had been absorbed from the anterior chamber, which was again filled with aqueous humor. There had been no pain since the operation.

In the evening the fellow-eye became red and watery and slightly painful. The pupil was moderately dilated and sluggish, and the vision was blurred.

An opiate was given, and iced cloths were applied through the night, except during sleep.

The next morning the glaucomatous symptoms had entirely disappeared, and the vision was again $\frac{20}{30}$.

Two years later we saw the patient again. Both eyes had remained well.

R. V. = $\frac{20}{100}$ with — $\frac{1}{24}$.
L. V. = $\frac{20}{30}$: E.

A CONTRIBUTION OF FACTS

BEARING ON THE QUESTION OF THE DETERIORATION OF HUMANIZED VACCINE VIRUS.

BY DANIEL B. D. BEAVER, M.D.,
OF READING, PA.

THE following account of an outbreak of variola is presented as containing facts of general interest to the profession at this time, when so much is being said about the relative merits of humanized and bovine virus.

The circumstances attending the appearance and extension of the disease are unique in many features. It occurred in a rural district (among a class of people whose statements are more reliable than those of the class of persons who find their way into the small-pox hospitals of the large cities), where every inhabitant is personally known to the physician, and consequently every case could be traced to its origin, and when, furthermore, the manner of primary vaccination in nearly every case was known.

The facts were communicated to me by Dr. Thomas T. Zerby, of Sheafferstown, Lebanon Co., where the disease prevailed during the winter and early spring of 1875, and briefly mentioned by me in the report of the Medical Society of Berks County to the Medical Society of Pennsylvania. But since then

additional knowledge of the matter has been furnished, which leads me to record it in this journal.

The disease appeared first in a family living about three miles from Sheafferstown. The manner in which these people contracted the disease could not be discovered. They were attended by one of the village physicians, who during their illness was in the habit of taking a friend, Mr. F., with him on his drives. In the course of some days Mr. F. was taken sick suddenly with fever, delirium, unconsciousness, ecchymoses, etc., and died the second day of his illness. His death was supposed to have been caused by some obscure blood disease, and the corpse was kept the usual time, and during the funeral service taken into the church.

The funeral was largely attended, the number of persons there having been estimated at twelve hundred. Within a week after the burial of this man new cases of small-pox appeared in and around Sheafferstown, and the disease spread rapidly until the number of cases reached two hundred. The infection in every case was traced either to Mr. F.'s sick-room or his funeral, the latter, of course, being the origin of nearly all of them, since the duration of his illness was too short to admit of many persons visiting him.

Prior to his illness and burial there was no case of the disease in the vicinity of Sheafferstown, except in the family above mentioned.

Of the two hundred persons who became affected with the disease, one hundred and ninety-four bore vaccination marks, and six were known not to have been vaccinated. The latter were four small children, and two adults; the children all died, and the adults recovered, making the death-rate 66⅔ per. cent. Of the post-vaccinal cases only five succumbed to the disease, which left the mortality among them at 2½ per. cent.

These cases included persons of all ages, many of whom had not been vaccinated for many years, since revaccination is seldom practised in the rural districts of this section. Even during the prevalence of small-pox, comparatively few persons resort to it. For the primary operation, as well as for revaccination, nothing but the crust of humanized virus has been used for many years. The children are vaccinated during the months of May and June, because at that time of the year physicians have usually least to do, and the children are in better health than during the heat of summer, and exposed less to the changes and inclemency of the weather which give rise to inflammatory affections in fall and winter. It is then necessary for physicians to preserve virus from one spring-time to another. This is done by selecting good scabs, covering them with beeswax, and immersing them in glycerin or some other preservative fluid until needed. Thus one year's virus furnishes the supply with which to begin the work of the next.

In this way vaccination has been performed from year to year during the whole professional life of many of our oldest practitioners. The common rule of practice is, to vaccinate, and on the sixth to the ninth day visit the patient to ascertain whether it "has taken." If it has not been successful, the child is revaccinated, and, if this fails, the matter is postponed to some future and more favorable time, and often forgotten by both physician and parents. It must necessarily follow, then, that many of these persons are imperfectly vaccinated.

Notwithstanding all these deficiencies in the mode of vaccination, and the very severe exposure to the variolous poison of the persons who contracted the disease at Mr. F.'s funeral, the mortality compares favorably with that of other reports. It is even not much above that cited by one of the most active of recent assailants of humanized virus, Dr. Cameron, of Glasgow. He states that in eight thousand cases of post-vaccinal small-pox recorded in London, Edinburgh, France, and Copenhagen, between 1818 and 1830, the mortality was 1 per cent., and ascribes this favorable result to the fact that these reports cover a series of years which followed so closely upon Jenner's great discovery, that, as he says, "the lymph used was still comparatively fresh."[1] Whether this conclusion is correct or not, it is not within the province of this paper to question. It may be noticed, however, that Dr. Cameron does not take into account, in his argument, the well-established fact that methods of practice based upon recent discoveries are always more thoroughly executed during the years immediately succeeding their introduction, and the recognition of their value, than at a later period. Especially is this true of prophylactic measures, because at the beginning their usefulness is more apparent. Every one feels more keenly the importance of vaccinating carefully during the prevalence of small-pox than after its disappearance for some years; and so, undoubtedly, the same feeling led to a better performance of the operation soon after its introduction, when the widely-spread ravages of small-pox were yet fresh in the memory of many vaccinators, and when the new practice had yet to contend with inoculation, which was itself often as dangerous as the disease taken in the natural way. Now, after continuous observation, during more than three-fourths of a century of the efficacy of vaccination under every variety of conditions, we have become careless in the performance of it, which, although it may be taken as one of the best proofs of our confidence in its protective power, has probably been one of the principal causes of the increase of post-vaccinal small-pox. Furthermore, this remissness on the part of vaccinators has not only led to bad results in their own work, but has lowered the popular estimate of the importance of performing the operation thoroughly, until it has come to be regarded by many persons as so simple and trivial an affair that any one can execute it, and be the judge of its success, and given rise to the practice of self-vaccination. Instances of this kind, in which all the members of a family have been vaccinated by one of themselves, with virus obtained, perhaps, from the arm of a neighbor's child, are frequently observed in this city and the surrounding country. May it not be assumed, then, that there were many persons among the twelve hundred who attended Mr. F.'s funeral that were supposed to have been under the influence of the vaccine disease, who may

[1] London *Lancet*, American Reprint, p. 475, 1880.

have had marks on the arms, and yet were entirely unprotected against small-pox, simply because they had been carelessly vaccinated.

This being admitted, the deterioration of the protective influence of the humanized virus used in these one hundred and ninety-four cases, which was certainly very many removes from the cow, may be considered as almost *nil*, since the mortality of the whole number who bore vaccine marks was only $2\frac{4}{7}$ per cent. If none had died, it would have been said that the protection was perfect.

It seems reasonable to conclude, then, that the cause of death in the $2\frac{4}{7}$ per cent. of these cases was owing to imperfect performance of vaccination, carelessness in the selection of crusts, and neglect on the part of both physicians and patients in those instances in which a full development of the vaccine disease did not follow a first or second vaccination, rather than to any loss of vitality in the virus consequent upon its repeated passage through, and regeneration in, the human body.

REMARKS UPON SMALL-POX AND VACCINATION.

BY HARVEY L. BYRD, M.D.,
PRESIDENT, AND PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN IN BALTIMORE MEDICAL COLLEGE, BALTIMORE, MD.

THE prevalence of small-pox in so many portions of our country during the autumn and winter of the current year, would seem to render almost anything that might be said, looking to its amelioration or prophylaxis, particularly interesting to the profession at the present time.

The March (1881) issue of the *Independent Practitioner* contained an exceedingly practical article on the mode of vaccinating, from the pen of Dr. Barton Dozier, an intelligent young physician of Ukiah City, California; and as I have practised his method in about two hundred cases, I am prepared to speak of it in terms of genuine commendation. He says: "I use *only fresh bovine virus*, and prefer that on ivory points to any other. I dip the point to be used in *cold water*, then lay it aside, in order that the virus coating may become well dissolved or softened. In the interim, I scarify with a dry ivory point, stroking just hard enough to scrape off as completely as possible, *without bringing blood*, the cuticle or scarf-skin, for a space of about a quarter of an inch square. I then rub the previously prepared point over this abrasion, until the virus is all off, and insist on the sleeve being kept up for at least five minutes *after* the operation is completed." Dr. Dozier further recommends that "a piece of adhesive plaster of sufficient size to cover the scarification" should be applied before the sleeve is drawn down. He tells us that he "got as a result *ninety-seven* per cent. of successful vaccinations."

My own success has equalled his since I have adopted his method, and such of my professional friends as have pursued the plan of *scraping* off the cuticle, have been highly pleased with the results. In fact, I think it capable of affording more satisfaction than any other method whatsoever.

My failures have been absolutely *nil*, where the susceptibility to the action of vaccine virus had not been overcome by its previous introduction into the system, or an attack of variola, since I have adopted the course recommended above. I am fully satisfied, from long experience, that vaccination, when performed according to the usual methods, and with humanized virus, may be repeated successfully a number of times before the system is thoroughly *saturated* with it, or a point of complete immunity against an attack of variola is reached. I use the word saturated for the lack of a more expressive one, as I am entirely satisfied that when a certain point is reached, the system will receive no more impression from the virus; and then the protection against small-pox is perfect and absolute for all time to come. How often it may be necessary—if necessary at all—to repeat the process of vaccination by *scraping* off the epidermis and applying *bovine virus*, fresh from the cow, I am not prepared to say, as my experience in this way has been too brief. But when the point of saturation is reached, the system is fully protected against the invasion of variola.

Another interesting fact mentioned by writers on vaccination, has frequently been verified by my own observations, and the truth of which should be as widely disseminated as possible, viz., that vaccinia may be successfully introduced, and its protective power secured even in the very presence of variola, so to speak; and its influence against the latter relied upon implicitly. Thus, by way of illustration, a case of small-pox may occur, or is introduced into an unprotected, unvaccinated family, but should successful vaccination with bovine virus be immediately, or even within a few hours, performed upon the other members of the family or household, such persons will be protected entirely from the variola under which the patient labored. This fact I have verified in several instances, and would respectfully and confidently urge its adoption as a safe and reliable prophylactic against the small-pox germs or contagion, even after pustules have been fully developed, and free intercourse has taken place for several hours between the patient and unvaccinated persons. The more rapid saturation of the system by the vaccine virus, and consequently earlier development of the several phases, or stages, of that disease, than that of the variola germs, should always cause it to be resorted to with reliable bovine virus, whenever an unvaccinated person is brought into contact with one suffering with small-pox. I favor repeating vaccination from time to time, until it ceases to affect the system, and when this point is reached, I feel warranted in saying that the protection against small-pox is absolutely perfect; the dicta and illogical statements of the opponents of Jenner's immortal boon to the human race to the contrary notwithstanding.

ETHIDENE POISONING.

BY EDWARD T. REICHERT, M.D.,
FORMERLY DEMONSTRATOR OF EXPERIMENTAL THERAPEUTICS AND INSTRUCTOR IN EXPERIMENTAL PHYSIOLOGY IN THE POST-GRADUATE COURSE IN MEDICINE, UNIV. OF PENNA.

ETHIDENE, or what is more technically expressed as ethidene bichloride, has recently come into vogue

across the water, and has been used to a considerable extent since the researches of the British Medical Association Committee were published, with results in some instances, as might have been anticipated, of the most painful nature.

In a recent article[1] I protested against the indiscriminate use of chlorinated, brominated, and iodated anæsthetics, and showed that among the most dangerous of all properties possessed by anæsthetics in general were decided depressing effects on the heart, and their liability to act at times altogether out of proportion to the dose, and that both these properties were possessed to a very notable degree by the compounds containing either of the halogens as constituents. Special reference was made to the ethidene bichloride, and evidence given which decidedly indicated that this substance markedly depressed the heart, and moreover, that a death had already occurred from its use. Since the publication of this article, I have gathered more evidence to substantiate these statements.

A record of about three thousand administrations with a list of three deaths, and four cases in which the most alarming symptoms ensued, imperatively cries a halt to this sort of experimentation, and drives the very chloroform death-list to shame; and at the present rate, the size of the death-list from chloroform in comparison with that of ethidene will be as insignificant in its proportions as the ether death-list is to chloroform. Therefore, in order that the profession in this country may fully appreciate the grave perils attending the use of this new anæsthetic, I have appended a summary of the above cases:

CASE I.[2]—A lady, about sixty, had lost blood from a vascular growth of the urethra. Within the first two minutes of inhaling I felt the pulse become small, and removed the inhaler at once. She continued breathing regularly fifteen or twenty times, then the breathing intermitted; the pulse was now imperceptible. I used artificial respiration. She recovered in two minutes; the pulse remained feeble; but I kept her insensible by occasionally giving the bichloride during the operatton.

CASE II.[2]—A gentleman, aged thirty, was about being operated on for fistula. I gave nitrous oxide till he was stertorous, adding ethidene carefully. The pulse becoming small, I allowed fresh air for three inspirations. He then became delirious, and struggled, passing quickly into a state of opisthotonos. I allowed air till he had so far recovered as to speak, and then renewed the ethidene. As he became stertorous, I noticed the pulse became intermittent and stopped. I removed the inhaler; the breathing continued firm and regular. In about twenty seconds the pulse returned; the patient awoke in five minutes in glorious spirits, though covered with perspiration.

CASE III.[2]—An old gentleman had lost blood for a long time from piles. At first I had difficulty in making him breathe regularly. At last he commenced panting very quickly. As he began to snore, I noticed the pulse began to fail, and it stopped. I drew his head to the edge of the bed, allowed it to fall back, and drew forward the tongue, with my long finger passed into the pharynx. Artificial respiration was carried on for two minutes, when he recovered. He was put again in position, and I continued to keep him insensible by ethidene during the operation. In five minutes after it was over, he expressed his satisfaction in the liveliest manner.

CASE IV.[1]—A man was about to have an operation performed for hæmorrhoids. He was pale from a loss of blood which had been going on for six months. The heart sounds were normal. Being placed on the right side, with his knees drawn up, bichloride of ethidene was administered with the gas, and ether inhaled. He did not respire regularly at first, but he never coughed, and was not observed to swallow. After twelve or fourteen respirations he talked and commenced to struggle. The face-piece was then removed for a little distance from the face, to allow him to breathe some fresh air. The struggling and convulsive movement which followed interfered with the precise observations of the state of the pulse; when these had ceased there was hardly any pulse, and it soon disappeared, but he continued to breathe ten or twelve times in a satisfactory manner, and then a pause was noticed between the respirations. His head was immediately extended backwards and downwards over the edge of the bed, and the tongue drawn forward, whilst the feet were raised, and artificial respiration commenced. This, in about a minute, restored him so far as to cause him to try to speak in an indistinct manner, as a patient often does just before waking up. The pulse became distinct, all danger seemed past, and he was again placed in position for operating. In doing this, he seemed to raise his head voluntarily, and some more of the anæsthetic was about to be given, when the pulse was again noticed to be failing. Without loss of time, the artificial respiration was recommenced as before, and, during the first three minutes, there were several natural gasping inspirations, but the pulse was never felt again.

Autopsy.—Heart large and flabby, with the usual amount of fat on it; heart substance on section had the ordinary appearance of fatty degeneration. The lungs were a little emphysematous and congested posteriorly, but fairly crepitant. Microscopical examination of the apex of the heart, including the extremities of both ventricles, was found to have undergone extensive fatty degeneration.

CASE V.[2]—A man, aged forty-five, was suffering from effusion into the right pleura cavity, and, after having determined that he was suffering from pyæmia, it was decided to give ethidene. During its administration the patient struggled a good deal, but nothing alarming occurred until he was "under," when it became necessary to turn him over on the left side and make an incision. He had not been in this position over two seconds when the pulse and respiration were found to be failing, and the pupils were noted to be widely dilated. He was then immediately turned on his back, artificial respiration commenced, and stimulants freely applied to the heart; first, by slapping the cardiac region with the hand, and afterwards, by a needle and galvanic current, but the only result was to get one long inspiration.

Autopsy.—The right auricle and ventricle contained much dark fluid blood; the tricuspid valve admitted four fingers. The left ventricle was empty. Microscopical examination of the heart showed no fatty degeneration. Other points of the autopsy are not of interest in this connection.

CASE VI.[3]—A boy, aged nine, was placed on the operating-table for operation of peritomy. Ethidene was given, and he was brought under its influence quietly and quickly. He then vomited freely, and more ethidene was given, but it was observed that his pulse

[1] Am. Journ. Med. Sciences, July, 1881.

[1] Clover, Brit. Med. Journ., 1880, I., p. 797.
[2] Mouillot, Brit. Med. Journ., 1881, I., p. 385.
[3] Everard, Brit. Med. Journ., 1881, I., p. 431.

became weak and fluttering, but rapidly recovering on stopping the ethidene. On resuming the ethidene anæsthesia was induced in about twenty seconds, and the operation commenced. It was very nearly completed when the pulse became almost imperceptible, and ceased entirely, together with the respiration; the face became cyanotic and congested, and the pupils widely dilated. The head was promptly but deliberately lowered, the chin drawn away from the sternum, and complete inversion of the body practised by suspending the child by the feet. He showed no signs of life for two minutes, when a long, deep gasp ensued, followed by renewed and deeper lividity of the face. In another minute another deep gasp ensued, and finally, by interrupted pressure over the cardiac region and lower ribs, the respiration and circulation were completely established.

CASE VII.—This case, in which death ensued, occurred in Berlin, and was reported by Kappeler in Part XX. of Billroth and Luecke's *Surgery*. I am, unfortunately, unable to give the details.

It will be noticed in reviewing the above cases that in every one of them, except the last, in which no details are given, there was a manifest and unmistakable failure of the heart, and that both deaths were due to this cause. In each of the other four cases the pulse had entirely ceased, and it was only by the efforts of the attendants that the heart's action was restored. It is also a noticeable fact, that while the above experimentors appreciated the depressant action of the drug on the heart, yet in not a single instance is there any evidence to show that any of them were aware of the fact that amyl nitrite had proved so beneficial in chloroform poisoning and other states of cardiac depression, or that its use was even thought of in case of accident during their rash procedures. Ethidene was abandoned by Snow on account of its dangerousness, and every investigator since his time must have appreciated the truth of his belief. The experimental researches of the British Medical Association Committee and Reeve have clearly demonstrated a decided depressant action on the circulation, and notwithstanding the fact that the above Committee were lead to anticipate from the results of the experiments on animals that there was a danger of cardiac failure, they, after making six experiments on man, reached the unwarrantable conclusion, that the anæsthetic "presents all the advantages of ether, without any of its disadvantages." The Committee state that in these six experiments no failure of cardiac action was present, yet their own, and also Reeve's, experiments on animals, as well as the evidence of Liebrich, Steffen, Clover, Hodges, and Mouillot, who have used the anæsthetic on man, all testify to the contrary. Hodges even thinks that it more quickly and markedly depresses the heart than chloroform, but the balance of the evidence goes to prove that it is not so powerful in this respect, and that it is not so dangerous. This is in accord with my own views, and I think that if the above four cases, in which recovery occurred, had been under chloroform, the chances of resuscitation would have been few indeed.

Our knowledge of the physiological action of ethidene indicates that its action is identical with that of the ethylene compounds, and having this fact in mind during a study of the latter preparation,[1] I considered it as the equivalent of ethylene bichloride, and stated that as an anæsthetic for general use the ethylene compound was undoubtedly superior to any yet introduced, with the exception of its isomer ethylidene chloride (ethidene bichloride) and ether, and was inferior to the latter in but the single point regarding the relative degree of safety, and that while it was probably equal to chloroform in strength, promptness, and permanency of effect, it was fully as much superior to it in a point of safety as it was inferior to ether, and that in case of accident following its use, the absence of the pulse at the wrist would not be so serious as under other circumstances. These deductions were the result of a careful study of direct experimental evidence, to which I will have to refer the reader, and I have had no sufficient reason since to alter my opinion, although the large percentage of deaths and accidents, as above given, makes it appear that ethidene is probably more dangerous than chloroform, but which cannot be so in view of our knowledge of its physiological action.

Ethidene is certainly a very dangerous anæsthetic, and should not be used except in cases where ether is contraindicated, and never without observing the precautions necessary in the use of chloroform, or without the amyl nitrite at hand.

HOSPITAL NOTES.

PHILADELPHIA HOSPITAL.

(Service of J. WILLIAM WHITE, M.D.,).

APPARENT PROTECTION FROM SYPHILIS AFFORDED BY PHAGEDÆNA.

(Reported by W. A. EDWARDS, M.D.)

CASE I.—John F., æt. fifty, was admitted to the venereal wards of the Philadelphia Hospital, on November 16, 1881. He was then suffering from a sore, which had appeared about six weeks previously, on the left side of the inner surface of the prepuce just posterior to the corona; in the left groin he had a very irritable sloughing bubo, about four inches in diameter. The sore presented the following appearances.

It was slightly elevated above the surface, the edges were sloping, its floor was grayish, and in places was covered by false membrane or a scaly exfoliation; the secretion was scanty and serous. The induration was very characteristic, firm, and cartilaginous, circumscribed and movable upon the surrounding tissues; this feeling was persistent throughout the case. There was no pain or tenderness. In other words it was a typical indurated or "infecting" chancre. The bubo, as before mentioned, was situated in the left groin about midway between the anterior superior spinous process of the ilium and the symphysis pubis. It was an open sore, highly inflamed and painful, the gland tissue being entirely broken down; its interior was covered with a grayish diphtheritic deposit, and its edges were everted and undermined. It was extending rapidly. The man was placed at perfect rest, iodoform was applied to the chancre, and a poultice to the bubo; after a few days the bubo was packed with lint saturated with a weak solution of sulphate of copper, about 4

[1] Phila. Med. Times, May, 1881.

grs. to ℥v.; all sinuses were opened as soon as they formed; this was continued for a short time, but the bubo continued to spread with great rapidity. The acid nitrate of mercury and a solution of the potassio-tartrate of iron were successively applied, but it steadily grew larger, dissecting above and below Poupart's ligament, exposing the external abdominal ring and bringing into view the sheath of the femoral vessels the pulsation of which could plainly be seen on the floor of the ulcer. The actual cautery also failed to arrest the progress of the ulceration, and in spite of tonics, good food, free stimulation and careful attention, the patient died on January 7. No *post-mortem* examination was obtainable. During all the stay in hospital the patient was carefully watched with a view to the recognition of any symptoms of constitutional syphilis. Although the average time for their appearance was far exceeded, ninety-five days after the appearance of the sore having elapsed, there was no evidence whatever, either cutaneous or glandular, of systemic infection.

CASE II.—Hermann S., æt. thirty; was admitted December 2, 1881. He presented a sore just within the meatus, involving both its lips, and which had appeared four weeks previously and about twelve days after intercourse. In the right groin was a very well-marked phagedenic bubo, extending over a large area and causing much destruction of tissue; its sinuses had been slit up before admission, and it had just ceased to spread. In this case, also, the sore had all the well-known characteristics of the initial lesion of syphilis. The sore and bubo were packed with a solution of sulphate of copper, 4 grs. to ℥i., and are now perfectly healed.

This patient, who is still under observation, more than three months having elapsed since the appearance of the sore, has shown no symptoms of secondary syphilis; the epitrochlear and post-cervical glands are not enlarged or indurated; the tonsils and pharynx are normal; no eruption of any description has shown itself.

Remarks.—The chief interest attached to these cases, as pointed out by Dr. White to the class, was in their relation to the conflicting theories as to the manner in which syphilis infected the system at large, and as to the true character of the primary sore; whether it is a local manifestation, as is claimed on the one hand, or the first symptom of constitutional disease, as is asserted on the other.

Admitting that the diagnosis was correct, and that the sores were of the kind that in the vast majority of cases is followed by easily recognized secondary symptoms, the absence of those symptoms is inexplicable, if the chancre be considered an evidence of systemic involvement.

If, however, the chancre be merely the result of local cell proliferation, at the point of original inoculation, and if from that locality the poison gradually find its way into the general circulation through the lymphatics of the penis and the groin, it can readily be imagined that such enormous destruction of tissue and complete elimination of glandular and other structures, as take place in phagedæna, might afford an actual protection from constitutional disease. Ricord and Fournier have both remarked as a clinical fact that phagedæna of the chancre often prevents syphilis from affecting the ganglia. It may be, therefore, that phagedæna of the ganglia exerts a similar influence in the further spread of the disease.

This view would seem to be corroborated by the results of the treatment of chancre by excision obtained by Dr. White, during this term of service, and which will be published when a sufficient number have been observed to permit of generalization.

MEDICAL PROGRESS.

ON A PECULIAR FORM OF GONORRHŒAL ARTHRITIS.—Two varieties of gonorrhœal arthritis are usually described. In the first of these, the serous, the knee is most often affected, but the ligaments and other tissues round the joint escape. In the second form pain, swelling, and redness are all more marked. The connection of the latter variety with gonorrhœa has been doubted, and some authors have regarded it as the rarer form of the two. DUPLAY and BRUN have arrived at a contrary opinion. They state that the second variety occurs with equal frequency in both sexes, that there is no relation between the severity of the urethritis and that of the articular lesion, and that the wrist and elbow are the joints most often attacked. The knee, so often the seat of hydrops, is relatively but seldom affected by this severe form of arthritis. In general there is an incubative stage lasting some days, accompanied by painful tension in joints and muscles, which outwardly exhibit no change, and general depression. Then some particular joint becomes extremely painful and swollen. Pain, aggravated at night and rendered excruciating by pressure, is the first symptom. There is no intra-articular effusion, but extensive infiltration into the surrounding tissues is evidenced by tense and often widespread œdema of the cutaneous coverings. This condition may be mistaken for abscess, and incisions have been made, of course without evacuating pus. The pain on pressure over the line of the articulation, and, later on, crepitation during movement, help to distinguish this disease from phlegmon. The failure of salicylic acid in some cases excludes another source of error. The treatment consists solely in complete fixation of the joint by means of plaster-of-Paris bandages, the application of which is speedily followed by diminution of swelling and cessation of pain. After from four to six weeks the dressing may be removed and passive movements commenced. If, however, the plaster bandages be not applied till after the disease has existed some time, the joint, after their removal, will be found considerably stiffer, or even completely anchylosed. In some cases all treatment fails, and notwithstanding all that can be done, anchylosis results (Duplay and Brun, *Archiv Général de Med.*).—Riedel, in *Centralblatt für Chirurgie.—Edin. Med. Journ.*, Feb., 1882.

PHOSPHORUS AND ARSENIC POISONING.—An interesting series of researches on the pathological changes produced by phosphorus and arsenic poisoning have been communicated to the Société de Biologie by MM. CORNIL and BRAULT. The quantity of phosphorus was equivalent to that contained in four or five matches, or to five centigrammes of arsenious acid. Guinea-pigs to which this dose was given daily lived for four or five days, passing arsenious acid by the bowel and kidneys. The object of the investigation as regards the liver was to discover the seat of the initial lesions, and their mode of extension in the hepatic lobule. The normal liver cells, treated with osmic acid, are limited by a delicate membrane, which presents a double contour, and in the middle of the cavity is a nucleus, which is connected with the capsule by a delicate protoplasmic filament. Six hours after the ingestion of the first dose of phosphorus, the hepatic cells, which are situated at the periphery of the lobule, near the branches of the portal vein, are increased in size; their protoplasm is, as it were, liquefied, and contains albuminous granules and some fine fatty granules. This lesion gradually increases, but remains limited to the periphery of the lobule, until, at the end of twenty-four hours, the cells there are large and distended by albuminous and fatty

granules and globules, while those in the centre are almost unchanged, and two or three days after the commencement of the poisoning the dilated cells constitute a sort of reticulated zone in the periphery of the lobule, and the delicate septum which separates two adjacent cells may break down, so that their cavities become united. The biliary canals present no alteration, even catarrhal inflammation being absent. In arsenical poisoning the change in the liver presents an important difference. The fatty degeneration is less intense than in phosphorus poisoning; but, instead of being confined to the peripheral zone of cells, it is uniformly distributed throughout the lobule. The lesions in the lung produced by the two agents are identical, and consist in a primary fatty degeneration of the epithelial cells of the alveoli; they become large and prominent, filled with granules and driplets of fat, their nuclei being preserved. The cells ultimately become detached, and fall into the alveoli, where they are mingled with an exudation which contains many blood-corpuscles. The change is less constant in poisoning by phosphorus than by arsenic. The resulting exposure of the vessels seems to afford an explanation of the congestions and ecchymoses which are met with in the lung. Partial pulmonary lymphangitis was also found after death from arsenic. The lesions in the kidney are the same as those which have been before described. The epithelial cells of the convoluted tubes are swollen, and contain conspicuous fatty granules a few hours after the commencemt of the intoxication. The cavity of the tubules also contains an exudation which is colored by osmic acid. In cases of longer duration the fatty globules are larger, and the epithelial cells, instead of being sharply separated, are reduced to a uniform mass, more or less filling the tubules. In other organs fatty degeneration of the endothelium of the vessels was also found.—*Lancet*, Feb. 4, 1882.

THE OPTIC DISK IN INJURIES TO THE HEAD.—Dr. A. A. FOUCHER draws the following conclusions from his essay on this subject:

1. In spite of the presence of a papillary stasis due to a traumatic lesion of the brain, acuteness of vision may remain unaffected; hence the importance of an ophthalmoscopic examination of all cerebral injuries, whether vision is affected or not.

2. This vascular stasis, when taken alone, cannot inform us as to the nature or gravity of the cerebral lesion, and its absence does not show the absence of grave lesions of the cerebrum.

3. The only conclusion to be drawn from its presence is that the meningeal fluid is abnormally increased, and as a consequence intracranial pressure is increased, as shown by the compression of the sheath of the optic nerve.

4. This compression may be marked enough to interfere with the circulation of the nerve, and yet not severe enough to interrupt its functional activity.—*L' Union Méd. du Canada*, Jan., 1882.

TREATMENT OF HYPERTROPHY OF THE TONSILS BY IGNIPUNCTURE.—The removal of diseased tonsils by the help of the finger, ligature, cauterization by caustics or the actual cautery, are all methods which have fallen into disuse. In Europe, the bistoury only reckons a few partisans, amongst whom is one of great authority, M. de Saint-Germain. The treatment nowadays most in favor is excision, performed with the guillotine, which has given rise to very serious and often fatal hæmorrhages. It is now alleged that, with the thermo-cautery, this serious accident is no longer to be dreaded. M. KRISHABER, who has tried it during two years, and has collected more than forty cases (*Annales des Maladies de l' Oreille et du Larynx*, July, 1881), has never had any accident after this treatment, and the results obtained have been lasting. It is likewise a novel application of a method which he has found perfectly successful for granulations of the larynx and pharynx. He proceeds as follows: The patient is placed—firmly, if a child—as if for laryngoscopic examination, in front of the operator, the mouth open, the tongue held back by a large spatula, the bottom of the throat well illuminated. M. Krishaber generally uses Paquelin's narrow-pointed thermo-cautery, heated to red-heat. When it is only required to modify the nutrition of the gland, he gives preference to Trouvé's polyscopic galvano-cautery. The puncture of the gland, made as deeply as possible with the point of the instrument, should be repeated five or six times at each sitting. An interval of two or three days is left between the sittings, so as to allow the fall of the eschar, and to estimate the result. The operation is not at all painful, and pain, from burning, is rarely felt. Nothing need be administered after the operation, except, in some cases, a gargle of warm water, slightly carbolized.—*British Med. Journ.*, Jan. 28, 1882.

INJECTIONS OF AN ALKALINE SOLUTION OF SALT INTO THE VESSELS IN ACUTE ANÆMIA.—E. SCHWARZ (*Centbl. f. Gynäkol.*, No. 20, 1881) holds that in cases of death from sudden hæmorrhage the fatal result is due not so much to the loss of blood-corpuscles as to the sudden change in the relation between the quantity of the blood and the capacity of the containing vessels. He refers to Goltz's work in *Virchow's Archiv*, No. 29, "On the Tonicity of the Vessels and its Relation to the Blood-Current." The writer, after taking two-thirds of their blood from dogs, injected a solution of salt, and from the good results he obtained, recommends this method in the human subject, not only for the collapse following profuse hæmorrhage, but also for that caused by severe wounds or prolonged operations, as in abdominal surgery, in which latter case he attributes the collapse to paralysis of the abdominal muscles. He recommends that 500 cc. should be the minimum amount injected, and says that three or four times this amount would do no harm. J. J. BISCHOFF, in the same Journal (No. 23), refers to the above paper, and gives his case as an instance of the value on the human subject of what had been used experimentally on animals. The patient suffered from post-partum hæmorrhage; the pulse scarcely perceptible, 156; respirations 42, had cold extremities, and was very restless. A 6 per cent. solution of salt, with a few drops of caustic potash and soda, was injected into the left radial artery in the direction of the blood-current, and the wounded vessel subsequently tied at both ends. A blunt vulcanite cannula, previously rendered aseptic, was employed. In the course of an hour 1250 fluid grammes was thrown in at a pressure of a column 58 to 60 cc. high. During the injection the patient revived, the pulse sank to 122, and she became quiet. Ultimately she recovered perfectly. It was noticed that meanwhile the hands regained their natural color and sensibility. The writer recommends similar treatment in cases where the blood-forming glands are healthy, but where there has been a sudden diminution in the quantity of blood, he suggests that even greater quantities of fluid might be injected, the injections to be continued from time to time till good results are obtained.—*Edin. Med. Journ.*, Jan., 1882.

IMPURE CHLOROFORM.—M. LUCAS-CHAMPIONNIÈRE has lately read a paper at the Paris Société de Chirurgie entitled "Etudes sur la Chloroformes." In it he states that Sédillot, who took great trouble to obtain pure chloroform, never had any accidents during its use. M. Perrin, in 1878, called the attention of the Academy

to the changes in chloroform. Wishing to remove hæmorrhoids with the *écraseur*, M. Lucas-Championnière anæsthetized his patient. All went well; but an hour afterwards a violent rigor supervened; in the evening, the patient was doing well. Four days afterwards, M. Championnière undertook the removal of a subcutaneous lipoma, near the scapula; the patient was chloroformed, and had a rigor like the one above mentioned. All the patients operated upon under chloroform at that time suffered from rigors. When the chloroform was changed, this symptom no longer appeared. In lying-in women, with certain kinds of chloroform it is impossible to produce hemianæsthesia. It becomes, then, a question, what are the substances which change the chloroform? On the 5th of July last, M. Lucas-Championnière performed the operation of radical cure of a very large right inguinal hernia, in a woman. Chloroform was administered; the respiration stopped. The patient was inverted, and artificial respiration applied; respiration returned at the end of four minutes. The chemist to the hospital declared that the chloroform was pure. Later on, in the same hospital, a youth, eighteen years of age, could not be anæsthetized; respiration stopped and necessitated inversion. Three days afterwards, with another kind of chloroform, the same patient could not be anæsthetized; but this time he became cold. On the next day, he was anæsthetized with another kind of chloroform. The first chloroform was examined by a distinguished Parisian chemist; the boiling-point was found to be modified; this chloroform was, therefore, impure, although the ordinary reagents testified to its purity. Permanganate of potash passes from red to green, if chloroform contain organic substances. With these reagents, M. Lucas-Championnière has found that throughout Paris there was no pure chloroform, although some specimens were almost pure.—*British Med. Journ.*, Jan. 14, 1882.

A Remarkable Gun-shot Wound of the Abdomen.—Dr. J. A. Rafter reports a remarkable case of gun-shot wound of the abdomen of a boy fifteen years old. The charge of a shot-gun, discharged about a foot from his body, entered the abdomen two and one half inches to the left and two inches below the umbilicus, making a terrible-looking opening, nine and one-half inches in circumference, tearing away the abdominal muscles to that extent, and leaving his intestines exposed and powder-burnt, and the intestinal liquid was plainly to be seen oozing from them at several points.

On turning him over, it was found that the charge had passed through him, shattering the ilium, and coming out at a slightly lower level than it had entered, and a trifle nearer the lateral aspect of the body. The posterior wound was the smaller; its lips were protruding and lacerated, due to the lodgment of gun-wadding, pieces of coat, vest, pantaloons, and shirt, which had been driven through him. When Dr. Rafter again examined the anterior wound, he found that considerable fecal gas and fluid had escaped from it.

The treatment ordered was nutritious diet, all the milk and brandy the patient's stomach would bear, and opium enough to check all peristaltic action, and keep him perfectly quiet. The case recovered.—*Med. Record*, Jan. 21, 1882.

Treatment of Rupture of the Uterus by Drainage.—In a recent number of the *Archiv für Gynäkologie*, Dr. Felsenreich reports a successful case. To understand why a treatment succeeds, we must know why patients not treated die, and what unfavorable condition it is that the treatment removes. Now, the peritoneum has a great power of absorption, and, by exudation of organizable lymph, of encapsuling and shutting off foreign matter from the general peritoneal cavity. There is no evidence that liquor amnii in the peritoneum is particularly hurtful, and large quantities of blood may be effused without causing peritonitis. There therefore seems no reason why the mere presence of the child, of blood, and of liquor amnii in the peritoneal cavity should not be tolerated. And as to drainage, the experience of ovariotomists tend to show that under ordinary conditions the peritoneum will recover from the effects of surgical interference better without the drainage-tube than with it. The special service which drainage renders in rupture of the uterus is probably this: the peritoneum not merely has to dispose of some amount of blood and perhaps liquor amnii effused into it, and to repair a solution of its continuity; in addition, there is constantly being poured into it, through the rent, secretion from the interior of the uterus, as well as from the wound, and these secretions partly accumulate and decompose. It is these decomposing fluids which excite inflammation, and drainage, by keeping open a channel for their escape, and so preventing their stagnation, gives the patient a better chance of recovery.—*Med. Times and Gaz.*, Jan. 7, 1882.

Treatment of Snake-bites.—Mr. Vincent Richards offers the following suggestions as to the treatment of snake-bites:

1. In the case of the bite being on a limb, a ligature should be at once applied above the bitten part, care being taken that it is sufficiently tight to prevent any blood being taken up into the general circulation from the distal end. Give a full dose of opium—40 minims of the tincture—or half a grain of morphia hypodermically.

2. Inject hypodermically into the bitten part a solution of permanganate of potash—4 grains to one drachm of water—and well press the parts with the fingers.

3. Open a vein below the bitten part, and wind round the limb an elastic bandage so as to exsanguinate the limb below the bitten part.

4. Cut through the bitten part and when dry apply pulverized permanganate of potash and then loosen the ligature. In the case of a person being bitten on the trunk, any treatment however prompt may be useless. Nevertheless it would be advisable to well inject the part with permanganate of potash, giving a full doze of opium as before recommended.

It may not be generally known to the members of the profession that a *poisonous* bite may be easily ascertained by cutting through the punctures into the areolar issue beneath, when if a red-currant jelly-like appearance is observable the bite is poisonous. The merit of pointing out the diagnostic value of this local appearance is due to Dr. Wall.—*Indian Med. Gaz.*, Jan. 21, 1882.

Genital Irritation.—From a study of nineteen cases, Dr. Landon Carter Gray believes:

1. That there is no proof that genital irritation can produce a reflex paralysis.

2. That while it is probable that slight nervous disorders, as incontinence, retention, difficult micturition, erratic movements, and slight nervous disturbances can be produced by genital irritation, the proof is not yet complete.

3. That operations for the removal of genital irritation may be beneficial even in organic nervous disease.

4. That we should, therefore, remove such genital irritation, if it exist in any case whatsoever, and thus give our patients the benefit of the doubt.

5. That in all cases of nervous disorders, with accompanying genital irritation, we should not regard the latter as the cause of the former until all other probable or even possible causes have been rigidly excluded.

6. That operations upon the genitals, even when there be no genital irritation, may prove to be a useful therapeutic measure in certain cases.—*Ann. of Anat. and Surg.*, Feb., 1882.

IODOFORM IN SURGERY.—In the *Berliner Klin. Woch.*, December 12, PRIVAT-DOCENT MIKULICZ terminates a paper upon the most recent employment of iodoform in Billroth's clinic with the statement that all the trials made with this substance justify the following conclusions: 1. Iodoform is, for all conditions in which the direct application of an antiseptic is indicated, an excellent means, deserving preference to all other substances hitherto used for this purpose. 2. The iodoform dressing may be used as a substitute for the carbolized gauze dressing of Lister, and is preferable to this on account of its simplicity and certainty. 3. The iodoform treatment admits of the antiseptic treatment of a wound, even under conditions that hitherto did not allow of a powerful antisepsis being pursued. 4. In wounds and ulcers already septically infected, iodoform, as a rule, operates more quickly and certainly than other antiseptics, while it does not irritate the tissues. 5. Iodoform acts in a specific manner on syphilitic, tubercular, scrofulous, and lupous infiltrations.—*Med. Times and Gaz.*, Jan. 7, 1882.

LITHOTRIPSY AND LITHOLAPAXY.—Prof. BILLROTH, in an address made before the Weiner k. k. Gesellsch. der Aerzte, stated that before the adoption of Bigelow's method he had performed lithotripsy in 43 cases; in 2 of these the operation had to be abandoned and lithotomy performed, while of the remaining 41, 9 died. The number of operations, the fatal cases included, averaged 3½ for each case, the length of the sittings being from 10 to 15 minutes. In 6 cases on which he had operated after Bigelow's method, the duration of the operation was prolonged to nearly two hours without causing any unfavorable result. The only patient which he had lost after litholapaxy had died from hæmo-globinuria produced by poisoning with chlorate of potassium.

Prof. DITTEL also stated that he had made use of this method in ten cases, in all with favorable results, and that he believed in future lithotomy would be restricted to children and to cases complicated by an encysted calculus.—*Centralb. f. d. Med. Wissen*, Dec. 24, 1881.

PILOCARPINE IN DIPHTHERIA.—M. ARCHAMBAULT has recently made a communication to the Société de Thérapeutique, and gives the results of this method of treatment in twenty cases occurring in children. He found that it was impossible to give pilocarpine hypodermically from the violent terror and prostration nearly always produced. He therefore administered the drug in the form of an injection. He finds that pilocarpine seems to facilitate somewhat the loosening of the false membranes, but that this is the best that can be said about it, and out of the twenty cases he lost twelve. M. Archambault states that in future he will abandon completely the use of this drug.—*Revue Scientifique*, Jan. 21, 1882.

PATHOLOGICAL ANATOMY OF THE SPINAL CORD IN PHOSPHORUS POISONING.—M. S. DANIELO, from researches on this subject, gives the following *résumé* of his conclusions:

1. The alterations of the spinal cord in phosphorus poisoning are of the nature of a myelitis, whether central (peri-ependymal) or diffuse.

2. In acute cases, deposits of blood pigment, noticed for the first time by the author, occur in the central nervous system.

3. Large doses of phosphorus cause a central myelitis through the whole extent of the cord, with the formation of blood extravasation and deposits of pigment. Smaller doses, frequently repeated, produce a diffuse myelitis involving both the gray and white matter.

4. By means of phosphorus, therefore, an inflammatory irritation either of the nature of a diffuse myelitis, occupying both the gray and white matter, or an inflammation confined to the gray matter, may be produced at will.

5. The nervous phenomena observed during life, may be attributed to one or the other of these forms of spinal inflammation.—*Bull. Gén. de Thérapeutique*, Jan. 15, 1882.

TREATMENT OF FRACTURE OF THE CLAVICLE WITH SILVER SUTURES.—The unsatisfactory results which ordinarily follow treatment of fractures of the clavicle, in spite of the numerous forms of apparatus at the service of the surgeon, have led Dr. LANGENBUCH to attempt the above method. He reports the case of a boy, ten years of age, with a fracture between the middle and outer third of the left clavicle, which he treated by cutting down on the seat of fracture and suturing the ends of the broken bone accurately together with silver wire, and the periosteal sac with catgut sutures; the wires being so twisted that the ends could not perforate the skin, the wound was treated antiseptically, the arm being fixed by a Desault bandage. An ideal result is said to have been obtained.—*Deutsche Med. Woch.*, Jan. 28, 1882.

MANIA ACCOMPANYING SCARLATINA.—Mr. R. B. MITCHELL reports in the *Edinburgh Med. Journal*, Feb., 1882, a case of violent mania, characterized by delusions, occurring in a woman, aged fifty years, during an attack of scarlatina. A similar case was mentioned in our issue of Jan. 7, p. 15.

WRITERS' CRAMP.—The treatment of functional spasmodic affections in general is so very unsatisfactory, that we should gladly welcome any substantial addition to our therapeutic knowledge from any quarter. M. WOLFF, a German teacher of writing, has earned for himself a considerable reputation by his skill in the treatment of this class of affections; and his success is attested by such authorities as Nussbaum, Bamberger, Benedikt, Billroth, and Esmarch. Hearing of the beneficial results of his system, M. Charcot invited him to Paris, and placed under his care two patients suffering from writers' cramp, who had been treated by himself and M. Vigouroux for some months without any improvement. M. Vigouroux has published the cases (*Le Progrès Médicale*, 1882, No. 3), and mentions that, after being handed over to M. Wolff, the first was cured in fifteen, and the second in thirteen days. M. Wolff's system consists in a combination of gymnastics and massage. He makes his patients execute movements in all directions with the affected hand for half an hour to an hour and a half at a time, three or four times a day; and, in addition, the muscles involved are stretched more or less forcibly three or four hundred times daily. He also uses massage and friction, and attaches considerable importance to percussing the affected muscles. The most essential part is the extension of the spasmodic muscles. He thinks, if no improvement is apparent after five or six sittings, the case should be abandoned. The method is worth imitating, though, as M. Vigouroux remarks, while M. Wolff generously explains his procedure, he cannot give us, at the same time, his experience, his practical skill, or that medical instinct which not only enabled him to devise his method, but guides him in its application.—*British Med. Journ.*, Jan. 28, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, FEBRUARY 25, 1882.

NATIONAL PUBLIC HEALTH LEGISLATION.

II. THE NATIONAL BOARD OF HEALTH.

FIVE bills, affecting the National Board of Health, have thus far been introduced during the present session of Congress.

One of these, which has passed the Senate and is now before the House, directs the National Board of Health to obtain pure vaccine virus, and to furnish it to all persons applying for it at cost price, and appropriates fifteen thousand dollars for that purpose. Upon this, it is only necessary to remark, that vaccine virus should be not only pure, but fresh; that it should, therefore, be sent direct from the farm to the consumer, and that the National Board would do much more good by having made frequent careful inspections of the establishments of persons furnishing vaccine virus for sale, and by publishing the results of these inspections, than it would by undertaking to buy and sell the article.

The other four bills relate more especially to the quarantine duties of the Board, and are substantially identical. We select for comment the latest one, namely, that introduced by Mr. Van Aernam, the Chairman of the House Committee on Public Health, numbered H. R. 4043, February 6, 1882, and entitled "A Bill to Prevent the Introduction of Contagious and Infectious Diseases into the United States."

The greater part of this bill is merely a repetition of the provisions of the original quarantine act passed in the spring of 1879; the author apparently thinking it better to present the whole original act, as it would appear if amended, than to present merely the provisions for the amendments desired. It is not easy to understand the changes which this bill would make in the powers and duties of the National Board of Health as regards quarantine, but from a careful comparison with the original act, with the annual reports and recommendations of the Board as regards this subject, and papers read by individual members of the Board before various associations, the following seems to be a fair statement of the case:

On the 1st of January, 1880, after the experience of one season's working of the quarantine act, the National Board of Health presented a report to Congress, concurring in certain recommendations made by a special committee of the National Academy of Science, of which Dr. S. Weir Mitchell, of this city, was chairman.

This Committee recommended "that the act to prevent the introduction of contagious and infectious diseases into the United States, approved June 2, 1879, should be so amended that, in order to enforce the penalties provided in that act for vessels which shall enter, or attempt to enter, ports of the United States in violation thereof, it shall not be necessary to show that the port of departure was at the precise time of departure of such vessel actually infected with contagious or infectious disease, nor that ten days of official promulgation in the port from which said vessel sailed, shall have been effected. It seems preferable that all vessels from foreign ports coming to ports in the United States, shall be required to have bills of health. It is also recommended that the medical officer, who has to serve in the office of the consul at a foreign port, may be either detailed by the President, or appointed by the Board at its discretion."

It does not appear that any action has ever been taken by Congress upon this conjoint recommendation of the Academy and the Board. The bill now under consideration attempts to avoid one of the difficulties met with under the working of the original act, by providing that a formal notification to foreign ports through the Department of State of the provisions of the act, and the rules and regulations made in pursuance thereof, has been made for at least ten days in the port is all that is needed to bring a vessel sailing from that port under the provisions of the law, provided contagious and infectious disease exists there.

This "notification through the State Department," is to take the place of the "official promulgation" in foreign ports required by the existing law, and which has made the law practically a dead letter for certain ports, and more especially those of Cuba, to guard against the dangers from which the law was mainly intended. Official promulgation is, it seems, something which can only be effected with the consent or by the authority of the government

of the port interested, and the Cuban government has thus far refused to give its consent; such consent is, however, not necessary to the notification provided in the present bill, so that this amendment is in accord with the recommendations above referred to. It is probable, however, that this amendment is in itself of comparatively small importance, so long as the proviso that bills of health are to be required only from ports in which contagious and infectious disease exist, remains in the law.

The proper course would seem to be that recommended by the committee of the National Academy, viz., that all vessels from foreign ports coming into ports of the United States, shall be required to have a bill of health, to be signed by the United States consular officers, which is the system of Portugal. The importance of this does not, however, depend so much upon its utility in preventing the importation of contagious diseases, as it does in the tendency which it would have to secure clean ships and the health of seamen; and it is from this point of view largely that we think the general government should legislate in this matter. The National Board of Health does not appear to have again called the attention of Congress to the difficulties in enforcing the act dependent upon the causes to which we have referred, and the reason for this, as given by Dr. Billings, in a paper read before the London Medical Congress, was that it was considered best "to obtain by conference between the nations most interested on international system of prompt and reliable information as to the sanitary condition of ports and ships, which information should in part be carried by the ship itself, in the form of a bill of health, and in part, in the case of a presumably affected ship, preceded in the form of a telegram."

In accordance with this view, the International Sanitary Conference met in Washington a year ago. The full proceedings of this conference have not yet been published, and with regard to the value of the results obtained from it, there seems to be some difference of opinion. It approved the new bill of health proposed by the National Board of Health, which is a simple description of the sanitary condition of the port and of the vessel without any reference to free pratique or quarantine, but we have not heard that, as yet, the actions of the conference have been given practical effect by any of the governments represented.

Mr. Van Aernam's bill also provides for the appointment, by the Board, of medical officers at certain foreign ports, as recommended by the committee of the Academy; and for the sending free through the mails of reports, etc., destined for the Board. It will be seen that very little change is proposed by the bill in question. It must be remembered, however, that the present so-called quarantine act is to be in force only four years from the date of its passage, in June, 1879. We presume, that if Mr. Van Aernam's bill becomes a law, it will practically do away with this limitation of time, although this is not certain in the absence of a special repealing clause.

BRIGHT'S DISEASE IN LIFE INSURANCE.

THE frequency of totally unsuspected Bright's disease is not slight, and for life insurance companies it is a very serious matter. A single undiscovered case may cost them five, ten, or even twenty-five thousand dollars. Every careful doctor knows that he meets constantly cases in which examination of the urine reveals a previously unknown, but evidently long-existing, Bright's disease, which, when discovered, is irremediable, and goes steadily, though it may be slowly, down to the grave. Most of our insurance companies insist on an examination of the urine in all applications for $10,000 or over; others, more wisely, set the minimum at $5000; but experience has shown that no risk whatever should be accepted without such an examination. Nay, more, we go so far as to say that prudence dictates that every person of forty years old and upwards should have the urine examined once a year, especially if he have the serious nervous strain which attends heavy business responsibilities or laborious professional work. We go to our dentist annually to see if our teeth need repairing, *i. e.*, to see if any unsuspected disease be arising. At the worst, if we neglected to do so, we would but lose our teeth after years, and have to replace them by a less convenient and more costly artificial set. But if the kidney become diseased ——?

It may be said that it would add largely to the cost of medical examinations. True; but, *per contra*, it would save twice or thrice, possibly tenfold, its cost, in the escape from risks that are sure to die within a very few years and entail large losses. One $5000 loss so avoided would pay the additional fee for 1200 or 1500 such examinations, and the latent disease is vastly more common than that.

THE FALLACIES OF HOMŒOPATHY.

WE are glad to see under the above title an excellent article for lay readers in the March number of the *North American Review*. It seems more than likely that the relations between the regular profession and the homœopaths are again to be made the subject of a discussion which will probably excite popular interest and criticism. It is, therefore, well that through some channel the public should be informed of the essential teachings of the homœopathic school and of its proper position viewed from a scientific standpoint.

The difficulty which invariably presents itself at

the outset in arguments directed against homœopathy, is accurately to define and limit the so-called "system," which in both principle and practice is variously represented by its advocates, who in turns, twists, evasions, and sudden changes of base, are only equalled by the famous *pulex irritans* of the immortal Irishman.

It may, however, be taken for granted that a belief in one or all of the following propositions is essential to constitute a true disciple of Hahnemann, and that if they are all palpably untrue, and their falsity is capable of scientific demonstration, his followers must lie under the suspicion of being deficient in either mental or moral calibre:

1. That diseases are dynamic changes in a vital principle, or, in other words, are spiritual entities not depending upon material substances.

2. That the cure of disease is most easily and completely effected by drugs the therapeutic action of which closely simulates the symptoms of the disease itself; and that the probability of a favorable result increases with the exactness of this resemblance or similarity.

3. That the power of drugs increases with their attenuation, which may be carried to an almost unlimited extent.

4. That trituration or agitation confers new and augmented power upon the drug so treated.

To use their own expressions, we may say then that the doctrines of the "spiritual principle" of disease, of "*similia similibus curantur*," of "infinitesimals," and of "potentization," either singly or collectively, constitute the foundation upon which the teachings and practice of homœopathy rest, and without which there would be no such school of medicine, and no such class of practitioners.

If this be true, it becomes important that we should be able to state clearly and intelligibly the grounds for our disbelief in these hypotheses, and for our rejection of them, and repudiation of their exponents.

The daily press and the community at large are, as a rule, misinformed as to the situation, and are much inclined to applaud the mistaken efforts at compromise on the part of some of the regular profession, or to set down to bigotry and professional jealousy the admirable and unwavering resistance which, for nearly a century, that profession, as a body, has shown to this as to all other forms of quackery.

The absurdity of these dogmas is now generally recognized, and we need not at present repeat their refutation; but even in our own ranks there are doubtless some busy practitioners who, while convinced of the fallacy of homœopathic doctrines, and of the feebleness or insincerity of their upholders, and mentally satisfied with the knowledge of their universal rejection by impartial scientific investigators throughout the world, have neglected so to inform themselves as to be able to state explicitly and succinctly their reasons for holding these opinions.

On this account we have called attention to the above-mentioned article as affording a clear and fairly complete review of the subject, so written as to be within the comprehension of every intelligent reader.

A NEW DANGER IN ANÆSTHESIA.

DR. GEORGE FISCHER, in the *Deutsche Zeitschrift für Chirurgie*, 1881, vol. xv., p. 188, relates a case illustrating a curious and novel danger in anæsthesia which, so far as we know, has not yet been recorded. A patient with a compound fracture of the thigh suddenly died during anæsthesia from chloroform. The chloroform was pure, no food or mucus was found in the mouth, the tongue had been drawn well forward, and on the first appearance of serious symptoms, when but little of the anæsthetic had been given, artificial respiration and electricity had been used, but in spite of all and from no known cause the patient died.

The autopsy explained it all. A piece of chewing tobacco was found in the larynx completely obstructing the glottis. Hereafter not only must the operator remove artificial teeth before giving an anæsthetic, but he must see that a tobacco-chewer has none of the beloved weed hidden in any remote corner of his mouth. At the University Hospital, in Philadelphia, we learn this precaution is always taken, since in one case lately a patient nearly died from the same cause.

TRACHELORRAPHY.

"OF the beneficial results of the operation of trachelorraphy, I must candidly admit that I am not now so sanguine as at first." So says Dr. Goodell, and we think the judgment of most gynecologists, if founded on any wide experience, will echo the sentiment. Our opinions, as well as our coats, are largely swayed by fashion. When Emmet first emphasized the importance of lacerations of the cervix, trachelorraphy was to be the panacea for the ills of women, if we had judged from reports of the marvellous results obtained by over-sanguine doctors in all parts of the country. "But," adds Dr. Goodell, "I now know better when to operate, and this fact I have learned: That nervous exhaustion and spinal irritation will evoke symptoms which others, as well as myself, have referred to cervical tears, but which were in no wise dependent on these lesions."

The operation has its sphere, and is a permanent gain to our surgical resources. But it will not do everything. The ebb-tide has set in. In time we shall know just how much it will do, and how much it will not.

THE NEW YORK CODE OF ETHICS.

WHILE the New York State Medical Society by the adoption of its new Code of Medical Ethics has deliberately severed its relations with the American Medical Association and the entire profession it represents, its action does not seem to be received with enthusiasm by the New York State Homœopathic Society, to whose members it has extended the hand of affiliation. Dr. Talcott, in his Presidential Address before the State Homœopathic Society, at its annual meeting in Albany, referred to "the remarks made by Dr. Jacobi, President of the Allopathic Society, at its meeting last week, assuming that the homœopathic school was deserting its principles for the sake of affiliating with their brethren of the dominant school, which he said was dominant no longer, as shown by their offer to consult with their formerly despised brethren. What has wrought this? Has Mohammed gone to the mountain, or the mountain come to Mohammed?"

In view of the fact that the new Code of Ethics of the New York State Medical Society is in direct antagonism to the views which the Society has held, without expressed dissatisfaction, for over a quarter of a century, and to the long-standing code accepted by every regular medical society in the United States, the question may well be asked, Was not its adoption on the same day that it was presented and for the first time made public, and without the members having had the opportunity to learn the views concerning it, of the constituency they represented, both precipitate and unwise?

It remains to be seen how far the sentiment of the four thousand five hundred regular physicians of the State is correctly represented by the hasty action of the fifty-two gentlemen whose votes have given them this new code, and isolated them from the profession of the country.

In England the subject of consultations with homœopaths has attracted of late considerable attention in connection with the case of the late Lord Beaconsfield, and the views of the profession were recently formulated in the resolution passed by the Royal College of Physicians, which has already been published (see number for January 21, p. 86). In another column we reprint from the pages of the *Lancet* an admirable article on "Quackery within the Profession," which deserves the widest publicity. It is so timely, and deals so properly with the subject, that we are sure its perusal will afford gratification to every reader of THE NEWS, and it well shows, as is formally maintained by the Royal College of Physicians of London, how impossible it is for an *honest* physician to consult with any one who trades upon designations implying a special system of treatment.

THE TRANSACTIONS OF THE INTERNATIONAL MEDICAL CONGRESS, LONDON, 1881.

WE have just received by post the four large octavos containing the transactions of the late International Medical Congress in London, prepared by the Hon. Secretary-General, Sir William MacCormac, assisted by Mr. Makins and the secretaries of the sections. We are glad to write *Sir* William, for any one who was present at the Congress is well aware that the wonderful smoothness of its machinery and its successful results are due above all to the untiring energy and marvellous tact of the Secretary-General. Were any other evidence needed of the fitness of the honor conferred upon him it would be found in the wonderful celerity with which these volumes have been issued. In less than five months after the Congress adjourned its entire transactions are issued. What a labor this involved will be seen in the following facts. There are nearly 2600 royal octavo pages, containing 450 papers published in English, French, and German, with 858 speeches from the discussions, all printed in English. These had to be written out, often after translation, submitted to the speakers for correction, many of the papers had to be judiciously condensed (and some were even omitted, a liberty we commend to other Hon. Secretaries-General), proof had to be read and re-read, 180 illustrations had to be prepared, and after all this was done came the printing, binding, sending a circular to all the members and medical journals giving information of the publication of the volumes, modes of payment, etc., addressing each volume, and the transmission by mail. All this has been done, and successfully done, in less than five months.

Of the contents of the volumes we cannot speak at present, except to say that they are worthy of the occasion and the authors. Could we say more?

LEGAL PROTECTION OF THE PUBLIC AGAINST CONTAGIOUS DISEASES.

WE are very glad to see that the Philadelphia Board of Health have taken action in the matter to which we alluded in our issue of the 4th inst. They have recommended to Councils ordinances to prevent the spread of contagious diseases and providing for fines, as follows:

"Twenty-five dollars for the use of a public conveyance, without notification to the owner, by any person suffering from a contagious disease; $50 for a public funeral; $25 against any victim of a contagious malady for entering any public street car or conveyance; the same for selling any bedding, carpets, or household effects from an infected residence; and a fine of $10 for failing to state the cause in authorizing the publication of a death notice under similar circumstances; letting any infected house, or

room in such house, renders the offender liable to a fine of $100." Clearly as to the first item the fine alone is not enough. The carriage should also be disinfected by the medical officer of the Board of Health free of charge, and a fine of $25 should be imposed on the owner, if it be used again before such disinfection.

We hope that all of our city readers will immediately use their influence with the members of Councils from their various wards, in order to have these reasonable and eminently necessary provisions made for the protection of the community.

REVIEWS.

CHEMICAL ANALYSIS OF THE URINE, BASED IN PART ON (CASSELMANN'S ANALYSE DES HARNES). By EDGAR F. SMITH, Ph.D., Asa Packer Professor of Chemistry in Muhlenberg College; JOHN MARSHALL, M.D., Demonstrator of Chemistry, Medical Department, University of Pennsylvania. With illustrations. 8vo, pp. 104. Philadelphia: Presley Blakiston, 1881.

It is not always pleasant for THE NEWS to tell the plain truth about books that come to it for review. But we think it would be far better for both the makers and buyers of books, if candor always ruled its action. It must not be supposed, therefore, that we mean to be unkind in the present case, because we feel called upon to tell the plain truth about the little book before us. Our first comment is that its style is atrocious; for example (p. 50), ". . . Albuminuria such as is observed in Bright's disease, in nephritis, neoplasma renis. The so-called Bellinic casts, pus sediments in acid reaction and a small quantity of neoplasms even, always distinguish each of these troubles introducing albumen."

Again, it is very apparent that the authors have had but little experience in the practice of medicine. What they say about clinical deductions, is gathered from German authors, and very badly gathered at that. Again, their description of tests is confusing, inexact, incomplete, and sometimes erroneous. Had they taken the pains to ascertain, they would have found that the indigo-carmine test for sugar is worthless, as the characteristic reaction may be obtained when there is no sugar present.

Again, a proper acquaintance with uric-acid crystals, or with the German language, would have prevented their falling into the error of translating from Hoffmann and Ultzmann's book (without any acknowledgments) *Wetzsteinform* as "Wetzstein's form," instead of *whetstone-shape*. A similar blunder in observation and in linguistics occurs where another clumsy translation states that calcium phosphate crystals are "keel-shaped," whereas, the crystals are, and *keilförmig* means, wedge-shaped!

We have not had time to hunt up all the sources of the authors' information, but if the rest are as badly translated as the writings of Ultzmann, the poor quality of this book is easy to account for.

In the matter of illustrations, we find that, with one or two exceptions, the plates are inferior copies of those in the beautiful atlas of Ultzmann and Hoffmann, for which they themselves made the drawings, but which are here credited to Casselmann.

On the whole, it looks to us as though Casselmann had made too free use of Ultzmann and Hoffmann's work, and Marshall and Smith had made too free use of Casselmann's.

In conclusion, we regret to be compelled to say that this applicant for scientific favor lacks the most important qualifications of a guide to either the student or the practitioner.

1. TWO CASES OF VARICOCELE, WITH UNDEVELOPED TESTICLE, WITH REMARKS ON THE NATURE OF VARICOCELE; AND
2. A CASE OF ANTISEPTIC OSTEOTOMY OF THE TIBIA, IN WHICH RAPIDLY FATAL CARBOLIC INTOXICATION OCCURRED. By A. PEARCE GOULD, M.S. Reprint from the London Clinical Society's Transactions for 1881. 8vo, pp. 23.

Whether a varicocele causes atrophy of the testicle, or whether it merely prevents the development of the testicle, is a mooted point, with the preponderance of authority in favor of the causal relation of the varicocele. Yet those who believe that the testicle is not atrophied, have Sir Astley Cooper and Sir James Paget to appeal to. The difficulty is in the establishment of the real facts, *i. e.*, whether the testicle was originally small and undeveloped before the varicocele began; or, whether, having been of good size and firmness, it wasted after the appearance of the varicocele, and became flabby, etc. The statements of patients are, as a rule, so little to be trusted, at least on a point requiring exact observation, that the facts elude us in nearly every case. Mr. Gould's cases all seem decidedly to favor the view that the varicocele has prevented the development of the testicle. As to the cause of varicocele, he believes that, in many cases at least, it is not due to internal pressure and want of external support, but is a real venous hypertrophy. He suggests as a reason for it, that at puberty, when the testicle rapidly develops, there may be a transference of the developmental stimulus from the testicle to the veins. Mr. Gould does not seem to be aware of the paper of Dr. John H. Brinton, of Philadelphia (*Amer. Journ. Med. Sci.*, July, 1856), in which he asserts that there is no valve at the junction of the left spermatic and renal veins, and that this is one of the factors in producing varicocele on the left side, as the right vein at its junction with the vena cava has one. Mr. Gould states that in "all cases" he has yet examined on the left side, a valve has been found, either single or double. We are not disposed to support our American confrère against facts, but certainly our experience coincides with his.

The case of a simple osteotomy in which apparently death followed from cutaneous absorption of the carbolic acid, is certainly both curious as showing the intolerance of some people to the acid, and instructive as to the proper treatment in all similar cases—the immediate removal of the dressing.

ZUR KENNTNIS DER MIKROKOKKEN BEI AKUTER INFECKTIOSER OSTEO-MYELITIS; MIKROKOKKENHERDE IM GELENKKNORPEL. Von MAX SCHULLER, in Greifswald.

MICROCOCCI IN ACUTE INFECTIOUS OSTEOMYELITIS; MICROCOCCI IN THE ARTICULAR CARTILAGE. Reprint from the *Centralbl. für Chir.*, 1881, No. 42.

The presence of the lower forms of life in many diseases is now a question that is being investigated with far more than the former vigor. Lücke, Klebs, and others have found micrococci in the marrow of the periosteum and the surrounding soft parts; a fact that Schüller not only confirms, but adds to it the discovery of their existence in the articular cartilages, where they cause the destruction of the tissue, and give

rise to small canals leading down to the diseased bones.

The subject is well worth further study for its possible explanation of the septic results so often following osteomyelitis.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, February 2, 1882.

E. L. DUER, M.D., PRESIDENT, IN THE CHAIR.

(*Concluded from page 198.*)

Death after Dilatation of the Cervix Uteri with a Laminaria-Tent.—Dr. B. F. BAER reported the following case: In September, 1880, I was asked by Dr. Ch. K. Mills to see Mrs. M. K. She was æt. thirty-two, and had had six children, the youngest having been born four years previously. The last labor had been tedious from uterine inertia, and was followed by a smart postpartum hæmorrhage. Since then she had suffered from a recurrence of metrorrhagia about every two weeks, lasting from a week to ten days, each time, and very profusely. The blood-loss was attended by severe uterine tenesmus. In the intervals between the hæmorrhages there was a constant mucous leucorrhœa. She complained of pain in the hypogastrium and back. Her appearance indicated anæmia and loss of flesh.

Physical examination elicited the following condition. The perineum was slightly lacerated and the vagina relaxed. The cervix uteri was large, soft from congestion, and lacerated bilaterally, with a swollen, everted, and abraded mucous membrane. The body of the uterus was hypertrophied and retroverted, with a slight flexion at the junction of the body and neck. At the point of flexion there was such rigidity of the posterior wall, probably from atrophy, that, when the uterus was replaced, it would return to its old position as soon as released. The sound passed three and a half inches, and proved the uterine cavity to be dilated, and its walls soft and rugous. The internal os, the point of flexion, was quite narrow.

This lady had received proper general medical treatment from her brother, who is a prominent physician, and from others, and during the year previous to coming under my care, she had received local treatment, but with no benefit, so far as the metrorrhagia was concerned.

I diagnosticated, as the cause of the hæmorrhages, a hypertrophied, granular condition of the endometrium, the result of subinvolution and retroversion of the uterus, with possibly a polypus.

The plan of treatment pursued was absolute rest, vaginal injections of hot water, reposition of the uterus by placing the patient in the knee-chest position and scarification of the cervix, followed by an application of Churchill's tincture of iodine once every six or seven days. Ergot and the tincture of nux vomica, with quinia and some other remedies, were administered internally. The constriction at the internal os made it difficult to medicate the cavity of the uterus properly, and it was thought more prudent to await the result of less radical measures. The result, however, was not gratifying, for the hæmorrhages continued to recur with as much, if not more, severity than before. I now introduced a laminaria-tent and allowed it to remain about twenty hours. I then removed it with some difficulty, for it was grasped firmly by the internal os, the contraction at which point it had failed to fully overcome. The canal was now patulous enough to permit me to pass the dull wire curette, with which I removed, very easily, a large quantity of hyperplastic or granular mucous membrane. But my patient's temperature was up to 100° before I removed the tent, and her general appearance indicated trouble ahead. It is sufficient for my purpose to state that, in spite of every effort to combat it, the temperature continued to rise and the case gave every evidence of septicæmia with metritis and perimetritis, and went from bad to worse, until death took place nearly three weeks after the introduction of the tent. Full precautions were taken to guard against septicæmia.

Why did my efforts to benefit this lady end so disastrously? Ought I to have waited, and given a further trial to less dangerous means of treatment? The patient had been in the care of a competent gentleman for a year before, and he had pursued that plan most faithfully, with no relief, and my own treatment of the case, before I introduced the tent, had continued over a period of two months, and with a like result; the patient was going downhill, and something more had to be done.

Was the result due to the use of the curette? I do not think so, for the material removed was soft and degenerated. It would have been bad practice to have allowed it to remain.

Should I have used a steel dilator instead of a tent? The tent was used for the purpose especially of softening the indurated tissue at the internal os. The steel dilator would not have done that; and it was very desirable that the os should be made patulous by softening of the tissues, so that the body would contract and disgorge the vessels in its walls. The steel dilator would not have fulfilled the indication so well, but it would have been a less dangerous means of dilatation.

Was the operation deferred too long, until, from the loss of blood, the vessels were eager to absorb any fluid which came within their reach, and the blood itself so disabled that it could not purify itself when poisoned? I believe that comes near the truth.

I do not report this case as an argument against the use of tents, but because I believe all such cases should be reported, so that we may not be led to regard dilatation of the cervix as a simple measure devoid of danger. This is the only case of death I have had to follow dilatation with the tent. I have never had a case of death follow dilatation with the steel instrument.

Dr. E. L. DUER described a method of preparing a sponge-tent expeditiously. Take a clean sponge of cylindrical form, dip it into melted wax or paraffine, and compress it into form as it cools. Tents may be introduced when the speculum and forceps are not at hand, by wrapping the string attached to the tent around the forefinger of the right hand, and inserting the thumb nail into the base of the tent. The first and second finger of the left hand are passed behind the cervix; the tent is then introduced into the os uteri, and the left hand being quickly transferred to the abdomen, counter-pressure is made and the tent forced home. Pain following the insertion of a tent is frequently the consequence of pressure upon the fundus, and if the tent be withdrawn about one-fourth of an inch, the pain will be relieved. The sponge-tent is, without doubt, one of the most powerful means for the reduction of uterine hypertrophy.

Dr. PAUL F. MUNDÉ agreed with Drs. Smith and Duer, that sponge-tents were indicated in uterine hypertrophy and granulations of the endometrium. He has never had any bad results from dilatation of the uterus by mechanical dilators of any form; but he has withdrawn very offensive sponge-tents after twenty-four hours' use, and feared danger might be near, and wished to avoid it. He can get tupelo-tents of any size; they dilate not too rapidly, but regularly and strongly, and he preferred to use them, as he was afraid of sponge-tents. He agreed with Dr. Smith as to the method of application. He always made use of three steps in the insertion of a tent. He placed the patient in Sim's

position. The cervix should be exposed properly, and seized by a tenaculum; then the tent being properly held in a strong forceps, is dipped first into a jar of liquefied carbolic acid, then into a jar of vaseline, and then rapidly passed into the previously cleansed uterine cavity; quickly, if the tent be not too large, for if there be any point for it to catch upon it will catch. At the end of twenty-four hours he always removed the tent, and they were very nasty sometimes. He always dreads some bad result, but has been fortunate so far, and has not seen any. He now uses the tupelo-tent, and treats it in the same manner that he previously did the sponge-tents. It is easily introduced, it becomes fastened in a few minutes, its effects are good, the patient does not complain of much pain, it does not imbibe so much as sponge, and does not sink into the uterine tissue as the latter does, but it is not so efficient in reducing the size of the hyperplastic uterus, for there is nothing else so good as sponge for that. After a tent is removed, the uterus should be thoroughly cleansed. In cases where the sponge was successful for the relief of sterility, a tupelo- or laminaria-tent would have probably done just as well. A sponge-tent increases discharge and causes local irritation, and its removal involves loss of epithelium, and for these reasons it is not generally so good for relief of sterility. As the sponge-tent is rough, it sticks, and is introduced with great difficulty, if it be of large size, in proportion to the calibre of the internal os. It is a maxim that a sponge-tent must not be introduced into a fresh wound, and does not the dilator or bougie cause a fresh wound? The sponge-tent is undoubtedly the best for hyperplasia, but all the other indications are filled by the laminaria- or tupelo-tents. He had experienced the same difficulty as Dr. Smith in the tapering-tent, and had, therefore, cut off the small end of the tent. A Molesworth dilator is open to the same objection in some cases, not dilating either os, but expanding largely in the space between; the conical-tent does the same thing; blunt sponges are very difficult to insert; the laminaria has dilated in the cavities of the cervix and body of the uterus with an hour-glass constriction at the internal os, and it was withdrawn with great difficulty. The tupelo-tent dilates more equally, and also more slowly. Sponge-tents are also hard to withdraw, and should be twisted before traction is made.

Dr. DUER suggested twisting in one direction only, allowing the grasping instrument to be drawn in by the shortening during twisting, until the tent was entirely loose. On one occasion, in his experience, a piece of tent broke off and remained inside the uterus, but it was extruded by uterine action, and was found in the vagina the next day.

Dr. J. CHESTON MORRIS had found out the uselessness of conical-tents, unless inserted in a reversed position; he prefers the cylindrical form. The cases of death from sponge-tents were probably due to the use of three successive tents, at intervals of twenty-four hours; he prefers to allow a tent to remain from forty-eight to seventy-two hours; he has never had any serious results, but in consequence of the tents being disagreeable and troublesome, he now uses Molesworth's dilator, and with great satisfaction; but they are badly made, they leak, and are apt to break under necessary pressure. In one case he burst three dilators before he succeeded in effecting complete dilatation. He agreed in the usefulness of this method of treatment for hyperplastic enlargement, and thinks that in many cases it acts in imitation of a miscarriage—expansion, then contraction with the aid of ergot will cure chronic metritis and enlargement. He is now using large soft-rubber stems to effect a similar purpose; they gradually overcome the resistance of the internal os and expand it. He has never used the tupelo-tent. In his opinion, it is far safer to allow a tent to remain two or three days than one only. In removing a tent, push in slightly at first, and then make traction with a curving motion. He thinks the position on the back far easier for introducing a tent than Sim's position. He has introduced tents in the manner described by Dr. Duer, without speculum or forceps.

Dr. MUNDÉ asked, Where should tents be applied? At the office? What should be done with the patient after the insertion of a tent? It is very reprehensible to introduce a tent unless a patient can be kept in bed for one or two days after the removal of the tent; this is a very important point. He is accustomed to introduce all tents in the Sim's position, and through Sim's speculum, and has not succeeded so well on the back because the tent easily becomes rough if not quickly pushed to its place. He introduces the sound, and frequently the hard stem on the back, pushing the uterus down over the stem by pressure above the pubes.

Dr. A. H. SMITH said that success in the treatment of sterility, by means of sponge-tents, depends upon the relation of the time of insertion to the menstrual period. If used just before the period, it dilates the uterus, and expends all its malign influence before the time at which the uterus is expected to receive the impregnated ovum. The tupelo-tent fails in fulfilling the indications, as it would not allow the flow to pass through it (unless perforated), and it could not pass beside it if large enough to be of benefit. He had commenced to use tupelo-tents when they were first introduced; he found them very spongy and soft, with slight dilating power, and easily constricted by the internal os; he did not find it to have any advantages over the laminaria- or sponge-tent. It has great powers of absorption, and had the appearance, when new, of having been used and dried again. According to Dr. Mundé, the tupelo-tents are much better made now, are hard, smooth, and have greater power.

Respecting the use of the bougie before inserting a tent. The bougie does not cause a tear or abrasion of the surface. The wax bougies are flexible, pointed, and graduated in form. He has never seen bleeding follow their use; he has never used a steel bougie. He considers that there is far less risk than from the use of mechanical dilators, of which he is much afraid.

There is no difficulty in introducing a cylindrical tent, as it dilates uniformly from end to end, and a smaller tent answers the purpose, as the important point is the internal os; that is where the largest amount of tent is needed. He prefers the position on the back, the relation of parts is more natural, and the uterus is more easily straightened by pressure on the fundus above the pubes, making introduction easier. Tents should never be introduced in the office; to do so is very reckless. The patient should be put to bed, and cleansing injections should be used.

On motion, the further discussion of mechanical dilators of the uterus was postponed to the stated meeting of March 2.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 16, 1882.

FORDYCE BARKER, M.D., PRESIDENT, IN THE CHAIR.

After various reports had been read and adopted, the PRESIDENT introduced the author of the scientific paper of the evening, Dr. A. A. SMITH, who proceeded to read his paper, entitled:

Clinical Observations upon Diabetes Mellitus, with Cases.

Detailed histories of five cases were presented, a summary of which is as follows:

First, all were cases of disturbances of the nervous system; in none was there injury or sudden

shock to the nervous system, but continuous mental strain; they all occurred in private practice, and among people exceptionally well-to-do. Second, all had disturbances of hepatic and gastric digestion. None had albuminuria, nor malaria, most were addicted to the use of alcohol. Two had a gouty tendency, three had none, and none had rheumatism. There was not great emaciation in four, it was great in one. None ever had any troubles with vision referable to the diabetic condition. None ever had any skin troubles either during the progress of the disease, or as a sequel. Hereditary tendency was traceable in only one, and that very remotely. There was in none any increase in appetite. In only two was there any great excess in the quantity of urine passed. Three gave a history of excessive thirst.

These cases, said Dr. Smith, seem to illustrate the necessity of selecting a plan of treatment and following it up persistently. The treatment adopted in all of the above cases was the same, and as follows: Codeia, one-fourth grain, gradually increased to one grain, three times a day, after meals. Also, the tincture of chloride of iron, twenty drops, three times a day, after meals, not increased. These patients were given a laxative pill consisting of aloes, nux vomica, rhubarb, and extract of hyoscyamus, sufficient to relieve constipation, which was a prominent symptom. They were furnished with a written diet list as follows: Vegetables, tomatoes, celery, cabbage, lettuce, cucumbers, pickles, spinach, radishes, mushrooms, cauliflower, asparagus, truffles, oyster plant, onions, watercress, olives, tea and coffee without sugar. Gluten bread made from the gluten flour of the New York Health Food Company, also almond-flour bread. They were allowed to drink as much water as desired, to take meats, fats, oils, cream, butter, poultry, fish, eggs, cheese, and permitted to drink milk. Of drinkables, brandy, whiskey, claret, burgundy, very dry sherry, the acid wines from the Rhine valley, were allowed. They were privileged to eat nuts of all kinds.

One patient was still under observation; four had entirely recovered. Of the four that had recovered, one had had no sugar in the urine for seven years, and three, none for two years. All had resumed their former occupations, and were as actively engaged in work as ever. Treatment was continued about four months after the disappearance of all evidences of sugar in the urine, and, for the most part, up to the present time the tincture of chloride of iron has been continued on account of the anæmia.

One of these patients was a lawyer, another a literary man; one, an artist; one, a railroad man, having charge of a large transportation business, and the fifth, a lady, living in her own home. Their respective ages were forty, forty-six, forty-nine, sixty, and sixty-three years.

The author of the paper was inclined to believe, admitting that diet probably played an important part, that codeia must also be given a very important place in the treatment of the disease. He referred to the fact that opium had probably been used since the second century, but he gave to Pavy the credit of having first suggested the use of codeia. Dr. Smith took the ground that certainly in the majority of cases diabetes has its origin in the nervous system. As an explanation of the good effects of codeia, he suggested its action as a direct sedative to the nervous system, not only in a general way, but to the pneumogastric nerve, accepting the theory that disturbances of the glycogenic function of the liver in diabetes was probably due to influences conveyed from the nervous system through the pneumogastric. He looks upon disturbances of the glycogenic function as entirely secondary. He has no sympathy with those observers that think codeia simply diminishes the quantity of sugar in the urine, and the quantity of urine, and has no permanent effect. Many cases are recorded apparently cured from the use of codeia, and now Dr. Smith adds four more, and one still under observation, with favorable progress thus far. He states there are probably many cases of diabetes mellitus which go unrecognized, and which, if treatment was begun sufficiently early, could be cured. In many instances patients affected with this disease did not seek the advice of a physician until organs were involved which made recovery impossible. Dr. Smith claimed that the fact that codeia acted beneficially in all these cases in which disturbances of digestion was a prominent feature, adds another argument to those already adduced in favor of a nervous origin of the disease; the explanation of this view being that, ordinarily, codeia produces slight disturbances of the digestive system, but in these cases its administration was immediately followed by improvement in digestion. The question was asked, Is it not probable that in cases of diabetes mellitus, in which emaciation occurs very rapidly, there is interference with the functions of the pancreas, either as cause or effect? Dr. Smith stated that in two of the cases related, he was much surprised upon examination of the urine to find sugar, and that probably the diagnosis in these cases would have remained obscure for some time longer if he had not conformed to his usual custom of examining the urine of almost every patient. The results of treatment in these five cases ought to encourage us to take a more cheerful view of diabetes than has been taken heretofore.

Dr. AUSTIN FLINT, Sr., responding to the request of the President to open the discussion, said, I am glad this disease was made the subject of a paper, for it possesses a good deal of interest as well as practical importance. Diabetes mellitus is either a disease of much greater frequency than formerly, or it is more frequently recognized than hitherto. I certainly have seen within the past five or six years almost more cases than in the whole of my previous life, and the number of histories that I have collected is so considerable, that I have decided to study them analytically, and make them the subject of a future paper. I suppose the disease was formerly very often overlooked, in the first place, for the reason mentioned in the paper, that examination of urine for sugar was not so common a practice as now, especially when there were no circumstances suggesting diabetes mellitus, physicians being contented to look for albumen and casts. Another reason is, that in some stages of the disease there may be no increase in the quantity of urine passed, or excessive thirst, or any other symptom to excite attention to its existence. I have met with several cases where the patient had been ill for a considerable time, and was suffering from some other disease, perhaps a fatal disease, at the time of coming under observation, in which an examination of the urine showed the presence of sugar. I could refer to several cases in this city in which, by a kind of accident, an examination of the urine was made without any fixed idea that this disease would be discovered, and it has been found to exist. I will mention one instance of this kind which occurred some time ago. A clergyman from another State, apparently in full health, came to me with this statement: "I want to state to you a symptom which I have, which may be the most trifling thing in the world, but it has given me some annoyance, so I have come to ask you about it." The symptom was a kind of itching in the penis, and to quote himself, "I have no confessions to make, but did not know but it might have some significance." At first I thought the matter was hardly worth while for consideration, but I finally made an examination of his urine and found it loaded with sugar. The patient recovered in a short time, and two years

have elapsed without a return of the disease. I, therefore, very strongly recommend the adoption of the plan referred to in Dr. Smith's paper, that of making an examination of the urine in all cases. I have seen a number of cases in which the quantity of urine and its specific gravity was not increased, and under these circumstances, not a notable degree of thirst. I am also glad to concur in the statement of Dr. Smith respecting the grounds for a favorable prognosis in a considerable number of cases of diabetes. I have notes of quite a number of cases in which the recoveries have been persistent. I have found that the dietetic treatment will cause the sugar in the urine to disappear or be reduced to a very small amount in a short space of time. In this connection, I will say that the important treatment seems to be dietetic, and I think that failure, in many cases, is due to want of thoroughness in its being carried out; I do not mean that patients do not rigidly adhere to the diet, but that the diet should be made to be satisfactory to the patient. My rule, for a considerable time, has been to give to these patients a list of every article of diet which they may take, and every article which they must not take, so that they can have it before them. If the physician be content with general statements, the treatment will be pretty sure not to be carried out. The great difficulty is in regard to bread; very few patients will eat bread containing no starch. They soon tire of it, and finally it becomes impossible for them to get along with it. I, therefore, give them an article which is not entirely free from starch, though it contains but little. This is prepared by the New York Health Food Company. With this they get along very well. If the matter of bread can be disposed of, the other articles of food are so varied that patients can make a satisfactory menu.

As regards medicinal treatment, I see from Dr. Smith's paper that he advocates the use of codeia, as recommended by Pavy. I have only used it as a form of opiate to relieve weariness of limbs, cramps, and insomnia. I have not depended on it for a cure. I suppose most present are informed of the remedy which has been suggested within the past few years, and advocated by Dr. Husted. I refer to the sulphide of calcium. I confess that I think he was led by his enthusiasm to overestimate the value of the remedy. Still, I have prescribed it in a considerable number of cases; and though I have not sufficient data from which to draw definite conclusions, yet I do feel that the remedy has a certain amount of curative power, and I commenced its use with a good deal of scepticism. I have used it in at least a dozen cases within the last eighteen months.

I will refer to one other point, and that is a toxical agency, in connection with sugar in the urine. I have met with several cases of this kind. The first was that of a gentleman from the South, who came to this city to purchase goods. He had diabetes, and his physician gave him a letter to me. Not feeling well enough to leave the hotel he sent the letter to me by a messenger, with a request that I call upon him. I did so, and found he had diabetes, but his general appearance was healthy. He had taken cold, complained of a sore throat, and had a little pharyngitis, but I did not attach the least gravity to his case. Afterwards he sent for me again, but it was not convenient for me to see him, and I sent my clinical assistant instead. My assistant soon returned, much alarmed, stating that he found the patient in a dying condition. I hastened to the hotel, but he had died before I reached there. I did not observe the symptoms in this case, and the only knowledge I have of them is a few general statements. It was certain that the urine was sufficiently abundant to eliminate the idea of death from ureamic poisoning.

Dr. Flint related the history of one other similar case, in which death occurred rather suddenly. Some attention had been given to this subject of late. He said there was certainly a liability to the development in this disease of some toxic lesion, which might destroy life in a very short time.

Referring to a favorable prognosis again, he said, I am cognizant of at least half a dozen persons in this city who have diabetes and who are in the enjoyment of comfortable health and doing laborious work, most of them finding it necessary to observe more or less strictly the dietetic treatment. With proper care and proper means, for it is pretty difficult for a poor man to carry out the treatment, I do believe, that by dietetics alone, in a certain number of cases, if not a complete cure, the holding of the disease in abeyance, will be effected, and the general health remain excellent.

Dr. HUBBARD was next called upon by the Chair, and remarked that he had seen several cases of diabetes, and now had two under treatment, one having been under treatment for four years, and the other for two. The dietetic treatment was being used in connection with the administration of yeast. In one case sugar had on several occasions disappeared from the urine. Both patients were ladies in easy circumstances, and had not had, to the Doctor's certain knowledge, any very great mental strain. The one who has been under treatment for four years is now in tolerable health. She had lost some flesh it was true, having been reduced from two hundred pounds to one hundred and seventy pounds. She is about fifty years of age. When treatment was commenced she was passing eight quarts of water. A tablespoonful of brewer's yeast was given three or four times a day. The case of a boy two years of age having diabetes was mentioned. Bicarbonate of soda was administered, but the patient died within a few months. None of the Doctor's cases had been cured, but some had been materially helped.

Dr. VIRGIL B. GIBNEY, being called upon by the Chair for his knowledge of the occurrence of diabetes in connection with organic diseases of the nervous system, said he knew of only one such case, that of a girl having infantile paralysis. In this patient diabetes did not develop until she was about fourteen years of age, at which time she had complete palsy of the right leg. She came of a decidedly neurotic family. She finally died of pulmonary œdema, but no definite connection between the diabetes and paralysis could be made out, and their co-existence was looked upon as an accident.

Dr. KINNICUT remarked that it seemed important to bear in mind that there are, apparently, two distinct forms of the affection. In one the patient can digest only a small quantity of sugar, and these cases can be readily controlled by strict dietetic treatment. In the other there is a serious diversion of the glycogenic function of the liver; and as these cases are never fully controlled, a guarded prognosis should be given. It is in these cases that very slight causes will produce that state known as diabetic coma, or collapse, in which the patient, almost without warning, passes into collapse, and dies.

Dr. PETERS had for many years adopted the view that the disease originated in the nervous system. Pricking the floor of the fourth ventricle would cause sugar to appear in the urine. Cutting the anterior roots would be followed by temporary diabetes. Cutting the posterior roots leads to a more severe and persistent form of the disease. Dr. Peters thought the basis of the disease was a vaso-motor paralysis in the severer forms, and a vaso-motor paresis in the milder forms. He had been in the habit of looking upon nux vomica as the best remedy. He had seen its use followed by benefit in a good many cases, and cure in some. He

concurred with Dr. Kinnicut in the view that in about one-half of the cases dietetic treatment was beneficial or curative; while in the other half, for the most part, only very slight benefit was to be derived from it. A strict anti-sugar diet might be adhered to, and all the symptoms go on. He thought in young children the disease was generally or frequently fatal. In advanced life it is milder, and much more amenable to treatment. In middle-aged subjects usually occurred the most serious cases. There were two large classes of patients. One, stout and obese; this class being quite manageable. The other, thin, nervous, and more or less debilitated, and very unmanageable. There were either two forms of the disease, or two stages, the first stage being manageable, the second stage being unmanageable.

The PRESIDENT alluded to a case, the history of which seemed to have some bearing on the etiology of the disease. The patient, a distinguished baron, distinguished as a poet, writer, and prominent member of the House of Lords, came to this country four years ago, bringing a letter of introduction from a most eminent physician of London, in which he stated the bearer had diabetes. The patient was seen the day after his arrival and was found excessively prostrated, and passing a large amount of urine—three or four quarts in the twenty-four hours. He was a very active man, a free liver, drinking abundantly of wine at meal-time which he supplemented with two or three glasses of water at bed-time. It was extremely difficult to restrict him to any diet, though he carried out the one prescribed to a considerable extent. He visited all parts of the United States, and during the time he was here the sugar in his urine diminished in quantity, and the quantity of urine passed became almost normal. He was permitted to satisfy his thirst by drinking all the water he wished. Since his return to Europe, Dr. Barker has had a long talk with his physician, who states that when his time is occupied with attendance upon great dinners, receptions, etc., he being very prominent socially, he very rarely suffers from diabetic symptoms, but after he has made a great public speech, as in the House of Lords, or has been engaged in historical or literary work, or bringing out a new edition of his poems, there would always be a great increase in the quantity of urine passed, and in the amount of sugar it contained. He would become excessively nervous and irritable. But after his intellectual work was finished and he resumed what we sober Americans might call dissipation, he apparently got well. He now enjoys pretty good health.

Dr. ALFRED C. POST inquired if any of the gentlemen present were informed as to the frequency of gangrenous troubles in connection with diabetes.

Dr. FLINT recalled to mind three cases of gangrene of the lower extremities in diabetic patients.

Dr. PETERS referred to a diabetic patient who received an injury to his great toe and died of gangrene.

Dr. WM. H. DRAPER said: I was unfortunate in coming so late as to be deprived of the pleasure of listening to the whole of Dr. Smith's paper; but from what I did hear, I judge he accepts the nervous theory of the origin of diabetes, and, it seems to me, we must all accept this theory when we consider the experimental researches made upon animals, and, also, when we consider the clinical history of cases of diabetes that come under our observation. There have been a very considerable number of cases of diabetes recorded as the result of traumatism of the brain, and in very many of the cases that come under the observation of the physician in his daily practice we can trace some nervous shock as the beginning of the disease. It would appear from the experimental researches, and from the clinical histories we have recorded, that the range of nervous irritation which will produce diabetes is extremely wide anatomically, and wide as to the cause of the irritation. But after all the liver appears to be the organ which is the chief instrument in the production of this disease. What remarks I have to make, sir, will be in regard to the association of diabetes with another form of disease, which is more common than diabetes, that disease which Bence Jones described as the "sour disease" in contradistinction to the "sweet disease." In other words, I think the clinical observations of most physicians will show that the great majority of cases of diabetes are associated with lithemia; that there is an error in the digestion of nitrogenous foods, as well as in the digestion of carbonaceous foods, in diabetic subjects. I think it can be shown that many cases of the grave form of diabetes, that form in which dietetic treatment does no good, give a hereditary history of gout, or have illustrated it in their own persons. It will be found, also, in these cases that there is not only sugar in the urine, but very often an excess of urea and uric acid. When we come to the consideration, however, of the milder forms of diabetes, the intermittent forms, I think this association becomes even more marked, because we can almost always in these cases trace in the individual some dyspeptic symptoms associated with gout, and we find in the urine, very frequently, deposits of uric acid and an excess of urea, as well as the presence of sugar. We shall find, also, in these cases, that the patients have been the subjects of true gouty lesions, of cutaneous lesions, of catarrhal lesions, of arthritic lesions. There is another circumstance in the history of these cases, which, it seems to me, goes to show the association of these two maladies, apart from hereditary influences, and apart from the occurrence in both of a similar kind of dyspepsia, in which there is an inability to digest any considerable quantity of carbonaceous foods, and that is, that diabetic and gouty patients are relieved by the same kind of diet, and by the same sort of medication. I think that those who have had much experience in the treatment of lithemia agree that a nitrogenous diet is the one upon which these patients thrive best, anomalous and paradoxical as it may seem to be. As to medication, I need only refer to the renown which alkaline springs have gained all over the world for the relief of both these classes of cases. Both classes of patients go to these places, and both get relief—victims of the sour and of the sweet disease.

I quite agree with Dr. Flint as to the importance of the dietetic management of diabetic patients, and think, until we can estimate the utility of medicines independently of diet, that it is not possible for us to exactly determine their value. I think it will be found that those medicines which have attained the greatest renown in the treatment of diabetes, outside of the alkalies, have been used in connection with dietetic treatment. Another point which I think bears upon the idea I have expressed, is the fact, that if we consider the different forms of medication used in the treatment of diabetes, we will find they are those forms more or less applicable to the treatment of functional disorders of the liver in gouty subjects. Aloes has already been alluded to as a useful remedy. Strychnia has been a remedy of great renown. Alkalies certainly have been of the greatest value in the treatment of the mild, and to a certain extent in the treatment of the severer, forms of diabetes. The cases which have been described by Dr. Smith certainly lend considerable support to the treatment by opium. With this remedy I have had very little experience, generally finding that diet would ameliorate the symptoms, and never having had any success or expectation of curing these cases, have not resorted to the use of drugs for that purpose. Dr. Pavy, I know, attaches a great deal of value to the use

of codeia, but Dr. Dickinson, equally distinguished, has not had the success attending its use that has been ascribed to it by Pavy. I have had some experience with the sulphide of calcium, and have been much pleased with the result, but never use it without prescribing a strict diet, and, therefore, cannot ascribe to it its true value. In the grave forms of the disease, where the patient manufactures sugar out of animal fats, I believe no treatment does any good. Here, I believe, we have a profound nervous lesion, what it is we do not know, which will prevent the utility of any medication.

Dr. SMITH, being called upon to summarize the remarks upon his paper, said: Mr. President, I shall have very little to say in closing the discussion. Although Dr. Draper was correct in supposing that I am of the opinion that the majority of cases of diabetes have their origin in the nervous system, I am not prepared to say that the disease may not have its origin in some organ in the body. Whether it is the liver that is first involved, and then the nervous system, or the reverse, I believe we have yet to find out. Since 1877, it has seemed to me, that in this direction, there are many observations to be made, and I look for the development of interesting facts in this line. I would say, then, I am not prepared to accept the idea that the etiology is always due to disturbance of the nervous system. I was somewhat surprised at the statement of Dr. Draper, that the same diet which would relieve diabetic patients would relieve gouty patients. I believe that gouty patients cannot digest meats as well as other patients. Diabetic patients can. The same is true, I believe, with other foods. I have no doubt but that diabetic patients and gouty patients are not able to take farinaceous foods, but, beyond that, I do not think we are able to trace the analogy.

In regard to codeia, I believe no one has touched upon the special point which I tried to make, that in grave cases as well as in mild cases, codeia was indicated. In those cases in which sugar is manufactured from food not containing sugar, or made from a meat diet, I contend that codeia places the nervous system in a condition in which sugar is not produced in such quantity. As bearing upon that point, I would call attention to the history of one of the cases contained in my paper, in which, though the dietetic treatment was continued all the time, when the codeia was withdrawn, the patient became worse, and improved when its administration was again begun. I admit that this is still almost theoretical, but it illustrates practically, at least to a slight degree, a point I have made theoretically.

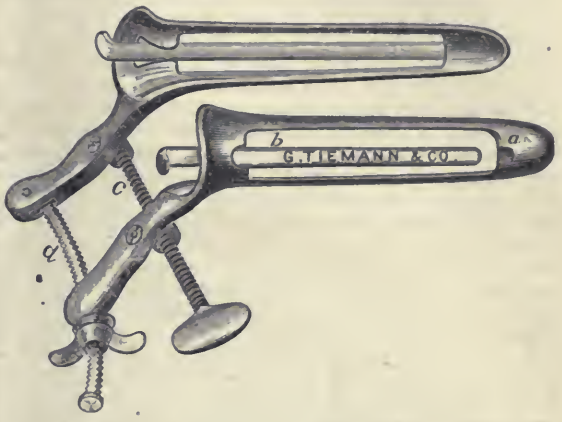
Upon motion, the Academy adjourned.

NEW INVENTIONS.

A NEW SPECULUM FOR THE RECTUM, AND ALSO FOR THE VAGINA IN THE VIRGIN.

BY W. W. KEEN, M.D.,
OF PHILADELPHIA.

I HAVE found the ordinary specula so unsatisfactory in the examination of the rectum that I have devised the present one to fulfil several purposes, and I have found it practically to answer admirably the objects I have had in view. The figure shows it of about three-fifths the full size, the length of the blades being three and three-quarter inches, the breadth, seven-eighths of an inch at the base. Placing the blades and handles in apposition, the blades are dilated at the base by the screw *c*, the ends remaining in contact and so forming a long Λ. This enables one to expose to view the anus and lower rectum, while the closed extremity prevents the escape of the fæces, unless they be very liquid. The value of this manœuvre in examinations for hæmorrhoids, fissures, and other anal troubles, or in any operations on piles is very obvious. If a lateral view of the rectum be desirable, one slide, *b*, or both may be withdrawn. *a* is a slot in which the extremity of the blade fits snugly when it is in place.



By screwing up the nut on the screw *d*, instead of *c*, the heel of the blades are a little dilated, but the chief dilatation is at the points. This will give a view of the rectum higher up. Or by using both screws, *c* and *d*, the blades may be dilated parallel to each other as in the engraving.

The small size of the speculum renders it admirably adapted for vaginal examinations in the virgin with the same variations in its manipulation as above described.

I must acknowledge the assistance rendered by Messrs. G. Tiemann & Co. in suggesting mechanical details which have improved this instrument.

CORRESPONDENCE.

HYPERMETROPIA IN THE PUBLIC SCHOOLS.

To the Editor of THE MEDICAL NEWS:

SIR: Any discussion of a medical subject which so widely affects the public interest as the condition of school life, must be, provided it be carried on with a spirit of fairness, both of interest and importance, and it is for this reason that I permit myself to add a few remarks to what has already been advanced.

I was sorry to see, from Dr. Randall's letter in THE MEDICAL NEWS, of February 4, that he was of the opinion that I meant to criticise Dr. Risley's work, published in the report on *Weak Eyes in the Public Schools*. This was not my intention, though if it had been, I had supposed that I was at liberty to do so. I certainly should have considered it a compliment if any work of mine had so impressed any of my colleagues, who had worked in the same line, as to render it worthy their serious attention and criticism.

This was not my intention, however; I merely wished to correct a statement which was not in accordance with the facts of the case, and one which Dr. Randall has himself characterized as loose. That it was a "loose statement" for a scientific paper, I do not think any one will deny.

Dr. Randall mentions the fact that I did not include in my list of foreign observers the statistics of Emmert (80.8 per cent.). This is true, for it was not necessary for the point which I wished to prove, but I am perfectly willing to do it now—and not only Emmert's enormous per cent. of 80, but also Scheiding's 25 per cent., and Koppe's 66 per cent.

This gives us eighteen foreign observers, and these

are all I know of. There may be others which I cannot find. If we add these to the former list, we then get as a combined result an average of hypermetropia equal to 21 per cent., or 1.5 times as much as my individual results; while, on the other hand, Dr. Risley's are nearly 3.5 times as large as the European average.

When, therefore, we see such tremendous discrepancies in the various examiners, for example, Dor, of Berne, 4 per cent., and Emmert, of the same place, 80 per cent., the conviction forces itself upon us that individual statistics are not of any value, and a great doubt arises in a candid mind whether the average of any and all are of any worth, so far as hypermetropia is concerned. When, moreover, we see such a careful and competent observer as Becker getting 12 per cent., and Emmert 80 per cent., the suspicion arises at once that the fault is not with the eyes examined, as much as with the method of examination. No one believes for a moment that when Dr. Derby and I get 13 per cent., and Dr. Risley 75 per cent., that there is six times as much hypermetropia in Philadelphia as in New York. Nor does this immense difference lie in errors made either on my part or on Dr. Risley's. I am quite sure if I had made my examinations in Philadelphia, I should have got a very much lower average, while Dr. Risley would have got a very much higher one here; and I feel quite convinced that some of the observers here would get 70 or 80 per cent. every time where I got 15 or 20 per cent.

These immense variations must strike an outsider, who is accustomed to look upon this branch of medicine as the most exact there is, as something preposterous; but, fortunately, it is not as bad as it looks, and depends mostly on the methods used, and the conception of what refraction really is, or rather what an emmetropic eye is. Strictly speaking, emmetropia is a mathematical point, and the slightest variation to either side of this makes either hypermetropia or myopia, and it is these small and trifling deviations which make the difference appear so large.

This brings me to a consideration of a point which I allude to all the more willingly as it was introduced by Dr. Randall, who observes in his letter that, while I give two of Cohn's examinations, where the percentage was 3 and 7, I omit his examination under atropia, where the percentage was over 88 per cent., "an omission no doubt accidental." On the contrary, the omission was intentional, as I should have been sorry to have made the mistake of comparing statistics made with atropia and those made without. The reason is that atropia always produces a temporary and artificial hypermetropia in the normal emmetropic eye, which, according to Donders, varies from $\frac{1}{100}$ to $\frac{1}{60}$. I alluded to this as long ago as 1866, and again in Philadelphia, in 1876, and Dr. Wadsworth, and Dr. Knapp, and others have called attention to it. Now, when we turn to Cohn's statistics in the original, we find that not only "was the percentage over 88," but that it was over 99 per cent., and that there was not a single emmetropic eye left. Cohn himself says, and he prints it in the largest possible type, "*Jeder scheinbare Emmetrop war nach Atropin hyperopisch*"—"Every eye apparently emmetropic was after atropia hyperopic." The only fair way, then, when atropia is used, is to discount the effect of the drug, and the question is what amount to allow for. I myself have taken $\frac{1}{60}$, which is about the medium between the extreme estimates made by Donders. It is supposed that this artificial hypermetropia is due to flattening of the lens; and this would appear to be corroborated by the examination made by Woinow, who found the radius of curvature of the lens of an eye, examined under atropia by the ophthalmometer, to be greater after its use than before. 9.74 mm. before, 10.10 after.

Then, again, some definite standard should be used. Dr. Derby and myself used, as stated in our work, $\frac{1}{60}$, either plus or minus, as the lowest variation from emmetropia which we thought would give an approximately fair result with school-children, and even then it often occurred that children with vision as sharp or sharper than the normal would still read Snellen xx. at twenty feet through $+\frac{1}{60}$, who were not hyperopic but emmetropic with the ophthalmoscope, and who, when tried, would always choose a plane glass in preference to the weak convex one. The mere fact that a young child sees xx. Snellen through a weak convex glass, does not show that it is hyperopic, as it may do this under weak circles of dispersion. Emmert himself says that out of his 80 per cent. "92 per cent. were hyperopic between $\frac{1}{72}$ and $\frac{1}{20}$, and that a great part, perhaps the greater part, are to be looked upon not as *pathologically*, but as *physiologically* hyperopic, and if we suppose a certain amount of negative accommodation, then a great quantity of the cases of *apparent* hypermetropia will be explained," and I cannot help thinking that this is the explanation of the phenomenal percentage that he and others get; and he further explains "that we have, therefore, an *accommodative* hyperopia, which should be distinguished from *actual* hyperopia—that is, *a departure from the normal form; a want of development.*" It was, I must admit, the actual, that is, a shortening of the axis, that I was after, and which I tried to obtain in my statistics, and I prefer to consider an eye which has no anatomical defect an emmetropic eye, rather than a "physiologically hypermetropic one," whatever that may mean. But some of my friends do not.

But to return to the standard. Emmert used $\frac{1}{72}$ as his limit. Cohn in some cases $\frac{1}{30}$, and in those under atropia, $\frac{1}{60}$. No wonder all his emmetropic cases showed H under atropia, especially as some of his children had a vision three times the normal, according to Snellen; a large quantity twice the normal; all over the normal except seven, and these seven the full amount. Dr. Derby and myself used $\frac{1}{60}$. It is not stated in Dr. Risley's elaborate report what standard he used, and no estimate can be formed of what the limit was, either by glasses or the ophthalmoscope.

Thus I would propose that when examinations are to be made in future, that some definite standard should be agreed upon, and that the effect of atropia, when used, should be accounted for, or, if not, then that every degree of error should be noted.

In my former letter I asserted that the same methods and same precautions were taken in Dr. Derby's and my examination and those of Dr. Risley. I find now that there was, however, a marked difference, for although the trial-glasses and ophthalmoscope were used in both cases, still they were differently employed. In my case, *every* eye was first examined with glasses, and its refractive condition noted, and then, without the result being known, it was examined with the ophthalmoscope. The two results were then compared, and if a discrepancy existed, a fresh examination was made, and in cases of any doubt, the preference was given to the glasses. This only occurred in very slight degrees. Thus, my results are practically a test by glasses. Dr. Risley's cases, on the contrary, were examined by the ophthalmoscope, and the refraction determined by that, with the exception that trial-glasses were used in doubtful cases. His results, therefore, are practically a test by the ophthalmoscope.

Now, as to the ophthalmoscope, with every incentive to look favorably upon it, and, while I consider it an indispensible agent in determining the nature of refraction, candor compels me to declare that I cannot consider the instrument as accurate a test as that by glasses. The "variables" are too many and too great

to make it, in my opinion, a safe guide when used alone in the lesser errors, a fact which I have always recognized and commented upon in various places, as, indeed, have others.

There are, of course, many things in Dr. Randall's letter which, were it of the slightest use, I might reply to, but discussions in regard to statistics, which seem to vary like the wind, are as endless as they are fruitless. I should, however, before taking leave of the subject, say that while I disagree in regard to the frequency of the occurrence of the various errors in refraction, notably the large amount of hypermetropia, I also disagree as to the phenomenal amount of conus in the normal as well as the abnormal eye. Thus, we find from table VI., in Dr. Risley's report, the percentage of conus, beginning at the enormous amount of 43.4 per cent. in emmetropic eyes, at eight years, and falling to 6.5 per cent. at seventeen; in the hyperopic eyes, from 41 to 22; and in the myopic, from 64 to 53. As conus is an anatomical change, the question arises, Where did the 37 per cent. of decrease in the emmetropic eye, for example, go to? It is stated that this frequency of conus, among other points, "was a genuine surprise to the Committee," and it certainly is to me, and I think will be to the ophthalmological world in general. Now, although there are these, and some other, points about which I disagree, there are many others, indeed most of the important ones, with which I not only agree, but to the truth of which, I, with others, have already testified at various times, in as an emphatic a way as was possible.

I am, respectfully yours,

EDWARD G. LORING.

NEW YORK, February 9, 1882.

NEWS ITEMS.

WASHINGTON.

(*From our Special Correspondent.*)

A MUSEUM OF HYGIENE.—The action of the American Public Health Association, which makes the Bureau of Medicine and Surgery of the United States Navy a permanent central repository for such material as may be placed in a museum of hygiene, promises to open up a new and important educational branch. Space has already been set apart for the purpose, directly under the control of Medical Inspector A. L. Gihon; and Surgeon-General Wales has recently issued a comprehensive circular asking for contributions and for the co-operation of all interested in sanitary matters, to make this attempt a success.

This undertaking represents another step taken in advance in the interests of technical education, so much needed in this country by the medical man, be he a graduate or undergraduate. The extent of ground which this museum will cover in time has, of course, not yet developed itself, but it is to be hoped that it will not be confined to the shutting up in glass cases of instruments that can readily be practically applied. Already the bureau has given us valuable and interesting practical work in this direction, of such a nature that it would not be just to refer to the labors of any one member of the corps individually; but the names of Gihon and Turner are most familiar to us at present, and Kidder can show us at the present site of the museum to-day valuable and interesting additions to the study of the atmosphere and its hygienic influences by his improvements upon and use of instruments for detecting the germs and spores of disease, and the permanent record of them by the aid of the photograph. This, coming as it does, coincident with the labors of the National Board of Health, and its reports from Smart, from Sternberg on the etiology of malarial fevers, and from Wood and Formad on diphtheria, taken together with the views regarding Listerism as expressed at the last International Congress, makes this branch of the subject at least of peculiar interest and importance.

All undertakings having for their object the teaching of the technique (for this word seems best to express it) of our profession would seem most to deserve encouragement in this country. Who knows but what the day may yet come when the ideal medical college will, by such means, be established; when the medical graduate receives his diploma, not because he has droned through three courses of lectures and crammed successfully at the last, but because he knows how to dissect, to make chemical and pharmaceutical preparations, to handle the apparatus of the physiological laboratory and record his results satisfactorily, to use the knife in surgical operations, and to diagnosticate and prescribe for living cases of disease, without reference to how long or how short a time he has taken to acquire this knowledge. Men may read of apparatus and study drawings without a clear appreciation of the same, which the handling and practical working of would give in a very short time. A man with a taste for practical applications in surgery soon learns how best to employ expedients, but not until he has seen the practical use of certain known instruments. And how many of our medical students really appreciate from what they pick up in a college course what all this talk of Pasteur, Tyndall, and others, about the germ theory, means? Their teacher in microscopy may show them bacteria and micrococci, and *perhaps* a few spores, but is not that all?

So, in answer to the cry from over the water of "fort mit Listerism," we would say "hoch" to the Museum of Hygiene.

DR. J. J. WOODWARD, with his family, sailed, on February 11, for Europe, with a leave of absence of eight months. It is his intention to go directly to Italy, and from there to Switzerland. A state of ill health, demanding serious attention, was necessary to force him to leave his official work upon the third and last volume of the *Medical History of the War of the Rebellion*, and to forego the pleasure of presiding over the coming meeting of the American Medical Association. Dr. Woodward has been abroad before for this purpose, but returned very much benefited. His present condition is said to be largely due to the constant strain and anxiety resulting from his attendance upon the late President during his prolonged and fatal illness.

Dr. P. O. Hooper, of Little Rock, Arkansas, as first Vice-President, will now become the presiding officer of the American Medical Association. He has been a member of the Association since 1875, is a member of the faculty of the College of Physicians and Surgeons of Little Rock, and was made a member of the Judicial Council of the Association in 1877.

BUFFALO.

(*From our Special Correspondent.*)

A STATEMENT has been going the rounds of the newspapers concerning the unhealthfulness of Buffalo, which is entirely without foundation in fact. The city is now, as it has always been, one of the healthiest towns of its size in the country. The mortality of Buffalo proper, is small, but some of its suburbs are in a very bad hygienic condition from the presence of slaughter houses, oleomargarine factories, and from cattle and pig-pens. In these localities, from four to five miles from the centre of the city, there is a good deal of disease from local causes, which the Board of Health is now trying to obviate.

INDIANAPOLIS.

(From our Special Correspondent.)

SMALL-POX has made its appearance in this city, two cases having been reported up to date. Stringent measures are being enforced by both the State and City Boards of Health, and the City Councils have passed an ordinance requiring every person who has not been vaccinated within the last ninety days to be vaccinated within the next ten days or be subject to fine. They also impose a fine upon any one having small-pox who does not hang out a red flag. An amusing instance of this occurred a few days ago. It was found that a case of small-pox was secreted on one of the principal streets and no flag was hung out. An order for the immediate arrest of the parties was issued, but the police were loth to serve it. The Mayor also thought it would be better policy to wait until the party recovered, rather than bring him out and subject the people to the contagion. A red flag is displayed at his residence now, but whether the family or the police put it up will ever be a mystery.

TYPHOID FEVER was not prevalent here as it was in other parts of the State, only a few cases having been reported. Its ravages were fearful in some of the rural districts. At Milroy, in Rush County, a town of three hundred inhabitants, about seventy-five cases appeared in the town in an area of two miles in diameter. Only six or seven cases died, however. Similar ravages are reported from all quarters of the State.

THE STATE BOARD OF HEALTH was fully organized January 1, with Dr. Thad. M. Stevens, Secretary and State Health Officer. The County Boards were also put in working order the first of the year. The Board issued an order that every person within the State must be vaccinated before the first day of February or be fined five dollars.

THE MEDICAL COLLEGE OF INDIANA has the largest class ever in attendance. The college building is new, and one of the best equipped in the West.

VIENNA.

(From our Special Correspondent.)

SURGICAL NOTES.—Prof. Theodor Billroth has recently returned from St. Petersburgh, where he was called to amputate the leg of Prince Czertkow. His fee was 15,000 florins, or about $6300.

Billroth has adopted the antiseptic method of Lister in a very modified form. He uses no spray apparatus, but in its stead floods the site of an operation with a 3 per cent. solution of carbolic acid in water. Instruments and the hands of the assistants are washed in a 5 per cent. solution. Catgut ligatures are employed. The universal antiseptic dressing for every form of wound is iodoform, in powder or gauze. This dressing was introduced into Vienna about one year ago by Mosetig and Johann Mikulicz, formerly Billroth's first clinical assistant and now privat-docent für chirurgie. The gauze is a coarse-meshed cotton fabric, deprived of vegetable oils; its meshes are filled with powdered iodoform, very much in the manner crinoline is treated with plaster of Paris to make a "plaster" roller.

"Immediately after the introduction of iodoform as an antiseptic remedy," says Billroth, "Viennese physicians and surgeons went to extremes and employed the remedy in large doses, internally and externally, for every form of disease and in every condition of life. Disastrous results, such as meningitis in children, albuminuria in adults, melancholia, febrile disturbances of serious character, collapse, at once appeared as the effects of this absurd practice. The remedy, then, was unreasonably totally rejected. Now, a healthy reaction in medical thought is setting in, and iodoform is assuming its proper position as a local antiseptic remedy, an invaluable adjuvant to carbolic acid—not, as König, of Göttingen, or Scheder, of Hamburg, says, a substitute." The odor of iodoform is well concealed by the bean, "tonka bona."

THE PUBLIC HEALTH.—The reports for the week ending February 18, so far as received, show the following returns of deaths from small-pox: Philadelphia, 17; Allegheny, 16; Huntingdon, Pa., 1; Montclair, N. J., 1; Cincinnati, 31; Milwaukee, 1. The disease has increased in Cincinnati, remained nearly stationary in Philadelphia, and decreased slightly in Hudson County, New York. Diphtheria is at present quite prevalent in Boston, 14 deaths from this cause being reported in the week ending February 18. In the same week there were 15 deaths from this cause in Philadelphia; 1 in Providence; 3 in Hudson County, New York; 2 in Cincinnati; and 1 in Milwaukee. Scarlet fever prevails in Hudson County, New York, there being 8 deaths reported there, against the same number in Philadelphia, 2 in Boston, 3 in Cincinnati, and 1 in Milwaukee. Typhoid fever caused 21 deaths in Philadelphia; 4 each in Cincinnati and Wheeling, W. V.; and 2 each in Hudson County, Boston, Richmond, and Milwaukee. One case of cerebro-spinal meningitis is reported from Milwaukee; and whooping-cough and measles are almost entirely absent from the mortuary records. No unusual prevalence of acute lung diseases is to be noted.

HEALTH IN MICHIGAN.—The reports to the State Board of Health for the week ending February 11, 1882, indicate that scarlet fever and tonsillitis have considerably increased, and that rheumatism, bronchitis, intermittent fever, diarrhœa, and neuralgia, have considerably decreased in area of prevalence. Special reports have been received, showing small-pox present during the week ending February 11, and since, at eleven places in Michigan, as follows: At Kalamazoo, Detroit, and Marshall, February 4; in Port Huron Township, February 5; in White Cloud, Newaygo County, February 6; in Kimball Township, St. Clair County, February 7; at Saginaw City (one case), February 7; at St. Joseph, on vessel (one case), February 11; at Spalding, Menominee County (eight cases, white), February 13; among the Indians at Indian Town, near Spalding (sixteen deaths and six cases up to), February 13; at Grand Rapids, February 14; at Parkville, St. Joseph County (one, convalescent), February 15, 1882.

HEALTH OF MILWAUKEE.—We are glad to learn that Milwaukee, although only 85 miles by rail from Chicago, with her death-rate of 134 for January, has had but 5 cases of small-pox.

THE NEW LIBRARY AND MUSEUM BUILDING FOR THE SURGEON-GENERAL'S OFFICE.—Dr. J. S. Billings, United States Army, in charge of the library of the Surgeon-General's office, appeared last Saturday before a sub-committee of the House Committee on Public Buildings and Grounds to-day and urged the necessity for a new building for the library, museum, and records of the Surgeon-General's office.

PROGRESS OF MEDICINE IN CHINA.—The late lamented Dr. Osgood completed, shortly before his death, a translation of Gray's *Anatomy* into the Chinese. He was threatened with brain disease for several months, and died suddenly while the work was passing through the press. As the Chinese have no ideas of anatomy, except what are purely conjectural, it was no simple task to make a translation, as special terms had to be introduced, and these again explained in a vocabulary.

Such a work will be of inestimable value to the native student, and have a tendency to open the eyes of others, in regard to the foolish conjectural teachings of their ancient sages.

Foreign physicians have now produced, for the Chinese, works upon anatomy, materia medica, chemistry, obstetrics, and several minor subjects. Dr. John G. Kerr, since his return to Canton, has entered upon the work left unfinished by Dr. Osgood, and is engaged, with the aid of two natives, who are all the time occupied, in making translations of other medical treatises.

Several physicians have recently arrived in China, to be located in Nanking, the Province of Canton, Swatow, and Formosa.

QUACKERY WITHIN THE PROFESSION.—The profession is probably unaware of the progress steadily made by medical quackery in its diverse forms and disguises. Quackery which is not medical—in the sense of being practised by duly qualified men—is undoubtedly an evil, but its consequences are not comparable with the effects of such quackery as is growing apace within our own ranks, and slowly it may be, but surely, undermining the respect and confidence which the profession has hitherto deserved and received from the public. We sometimes wonder that our calling does not command the warm recognition in certain quarters to which it seems entitled. For a sufficient explanation of this default in the estimation of society, let us look to the prevailing and almost daily increasing popularity of "systems" and "cures" tacitly, if not avowedly, supported or countenanced by the profession. There is a sentimental and mock-heroic spirit abroad which burlesques the candor of "truth-seeking," and even mimics the impulses of chivalry. We hesitate to condemn any system, "lest there should be some good in it," and we are too tender-hearted and polite to deal honestly by its promoters, even though we recognize the fallacy of their pretensions, and more than suspect their motives. This is not a faithful line of conduct in reference to our profession, nor is it loyal to science, which is one of the many constituent parts and aspects of truth. We know, or ought to know, that a perfectly just and truthful conception of the science of medicine must bar the recognition of *systems* and *cures* of any class or description. The art of healing is not a system, and can never be made one. It is simply an intelligent application of the laws of health in the remedy of disease. We study the "symptoms" of a malady with a view to the acquisition of precise knowledge as to its nature, course, and rational treatment. We pursue the investigation of disease over the boundary-line of death, and explore the cadaver with a view to ascertain the effect of the morbid state on the organism and to elicit its organic causes, albeit we too commonly confound effects with causes. We test the powers and analyze the constitution of drugs, and we scrutinize and make careful trial of methods of treatment, to obtain a reasonable acquaintance with their natures and actions. In brief, we take any amount of trouble and resort to every means at our disposal to render the principles and practice of our art *rational*. This is our duty, and it is the only method consistent with self-respect and professional integrity; but, if side by side with this policy, we cherish a spirit of credulity which renders us ever ready to countenance systems of which we can know nothing—because there is nothing to know—and take a false pride in showing friendliness to quacks and charlatans, the good work we ourselves may do is changed to evil by reason of the actual or implied sanction we give to the bad work done by others. Nothing is so much needed just now as the rise in our midst of a stern and uncompromising apostle of sincerity in science—a man of unpitying animosity to humbug in all its forms, who will not hesitate, at any bidding, to denounce wrong-doing and untruthfulness, let who may be the offender. It is time that a spirit of manliness went out in our ranks to chase away the lying spirit of mock courtesy—the faint-hearted and time-serving sentimentality—which makes us so ready to look kindly on any pretender, and so reluctant to expose any pretense.

There cannot possibly be a "system" or "cure" in medicine. There are no rule-of-thumb methods and no *mysteries* in true science. If we do not know what a remedy is, and how it acts, we have no right, as honest men, to employ it. The time has passed for the working of cures by charms and the recourse to nostrums. We pander to the credulity of the unskilled community when we show ourselves credulous. We patronize and encourage quackery when we extend professional recognition to a quack. Every man is a quack—whether qualified or unqualified—who employs a remedy without knowing why, or who adopts a "system" in medicine. The profession must speak out clearly and strongly on this point, and without delay. From the highest places in society to the lowest ranks of the people, there is just now a grievous readiness to "believe in" quacks and quackery. We have ourselves to thank for this most adverse "feeling" and "influence." It is the stirring of the viper we have brought in from the cold, where physicians and surgeons of more robust intelligence than those of to-day left it—the viper we have warmed and fed and brought back to life; and now it is preparing to rise and sting the hand that caressed it. The way to encounter the charlatanry which is making head against science is to be at once more candid and more conspicuously *honest* in our dealings with the public. We must lay aside the last vestige of the robe of mystery, and show by our words and works, our conduct and policy, that medicine is not a science that admits of inspiration, and that the practice of healing is not an art which can be acquired by the unlearned. There is no system or cure, or charm or nostrum, known to the profession; our calling consists solely in the rational study and treatment of disease on common-sense principles. For those who pretend to a sort of inspiration we have no professional friendship; and towards the promoters of systems and 'pathies we can have no leaning, or any feeling other than that of suspicion, if not pity and contempt. They can have no place in our professional intercourse, and we can have nothing to say to them or their work. This is the only sentiment worthy of the medical profession in its dealings with medical quacks, and the time has come when the revival of its old spirit is most earnestly to be desired.—*Lancet*.

HOMŒOPATHY AND THE BRITISH MEDICAL ASSOCIATION.—The Southwestern Branch of the British Medical Association does not, apparently, intend to allow the question of the relations existing between homœopathic practitioners and the Association to remain in its present unsatisfactory state. The subjoined resolutions were passed unanimously at the last quarterly meeting of the Branch, held at Plymouth, on December 31, under the presidency of Dr. Hudson, of Redruth:

"1. That this meeting desires to express its entire disapproval of the views, in relation to consultations with homœopathic practitioners, expressed by the readers of Addresses in Medicine and Surgery at the annual meeting of the Association at Ryde, in 1881.

"2. That this meeting desires to direct the attention of the Committee of Council of the Association to the resolutions in regard to homœopathic practitioners passed at the annual meeting of the Association in 1852, and reaffirmed at the annual meetings of 1858 and 1861;

and now calls upon the Committee of Council to put in force as speedily as possible By-law 3 against homœopaths and all members of the profession who assume designations implying the adoption of special modes of treatment."—*Lancet*, Feb. 4, 1882.

THE BURIAL-PLACE OF HARVEY.—The tower of the old church at Hempstead, in Essex, England, in which William Harvey is buried, fell down on the evening of Saturday, January 28, bringing with it nearly one-half of the roof and one arch from the south side of the nave, and letting down a good part of the roof of the south aisle. The vault in which Harvey lies is at the northwestern angle of the church, and is, consequently, uninjured. The church is supposed to have been built between the ninth and eleventh centuries. The medical profession of England and America are invited to subscribe towards the restoration of the building, which it is estimated will require about £5000. Subscriptions may be sent to Dr. B. W. Richardson, London.

VACCINE APPLIED TO SHEEP.—A Paris despatch to the London *Times* states that at a farm near Melun experiments were recently made by M. Pasteur in the presence of a host of specialists on the duration of the action of anthratic vaccine as applied to sheep. It will be remembered that six months ago M. Pasteur vaccinated a number of sheep with anthratic vaccine, the immediate result being to preserve all these sheep from anthratic virus, whereas sheep not so vaccinated succumbed within twenty-four hours to the latter. The question was how long the influence of such vaccine would last. The new experiments proved that it lasts six months, and they will be continued from month to month to ascertain the exact duration of the preservative. Four unvaccinated sheep were inoculated with anthratic virus, as also four of the sheep vaccinated six months ago. Two of the unvaccinated sheep expired within twenty-four hours, and the other two subsequently, whereas the sheep vaccinated six months ago admirably resisted the action of the virus. Another curious fact was ascertained. A lamb, the offspring of a vaccinated sheep, was inoculated with the virus. It expired within twenty-four hours, thus proving that the vaccine virtue is not transmitted hereditarily.

The Seine-et-Marne Agricultural Society presented M. Pasteur with a gold medal, and a banquet was held at which the great service rendered to agriculture by his discovery was warmly testified to.

MEDICAL DIPLOMAS IN FRANCE.—The six Medical Faculties in France have conferred the following diplomas during the school year 1880–81: The Faculty of Paris, 461; of Montpellier, 66; of Lyons, 44; of Nancy, 19; of Bordeaux, 18; and of Lille, 13. Total, 621.—*Med. Times and Gaz.*, Jan. 14, 1882.

HOSPITAL SUNDAY IN LONDON.—The collections this year amounted to $150,735, of which the Church of England gave eleven-fifteenths. All denominations—Jews, Greeks, Friends, etc.—are represented in the collection.

LECTURES OF THE ROYAL COLLEGE OF PHYSICIANS.—The following are the lectures of the Royal College of Physicians for the present year: Gulstonian Lectures, by William Ewart, M.B., March 3, 8, and 10, on "Pulmonary Cavities, their Origin, Growth, and Repair;" Croonian Lectures, by Sir Joseph Fayrer, K.C.S.I., M.D., March 15, 17, and 22, "On the Climate and Fevers of India;" Lumleian Lectures, by J. Burdon Sanderson, M.D., March 24, 29, and 31, "On the Pathology of Inflammation."—*British Med. Journ.*, Jan. 21, 1882.

OBITUARY.—Died, in Cologne, January 7, in the seventy-second year of his age, THEODOR SCHWANN. Schwann was born in Neuss-on-the-Rhine in 1810; was Professor of Physiology in Löwen from 1838 to 1848; and from 1848 up to the time of his death, Professor in Liège. With the name of Schwann, above all others, is associated the first conception of the cell-doctrine, the foundation and starting-point of modern physiology and pathology; and, although he distinguished himself in other work, it is as the founder of the cell-doctrine, as shown in his work on the *Structure and Mode of Growth of Plants*, published in 1839, that he will be remembered. From 1834 to 1839 he was the assistant of Johannes Müller.

— At Brooklyn, on February 12, THEODORE L. MASON, M.D., aged seventy-nine years. Dr. Mason graduated at the College of Physicians and Surgeons, New York, in 1825, and was for many years prominent in the affairs of the Long Island College Hospital, and of the Inebriate Asylum of Kings County.

— In this city, on the 20th instant, aged seventy-six, ROBERT BRIDGES, M.D., Emeritus Professor of Chemistry in the Philadelphia College of Pharmacy, and formerly President of the Academy of Natural Sciences, of Philadelphia.

NOTES AND QUERIES.

IS TYPHOID FEVER CONTAGIOUS?

To the Editor of THE MEDICAL NEWS:

SIR: Two months ago typhoid fever was imported into this village, at a time when there was not another case probably within five miles. Two weeks thereafter cases began to occur, first within it and then around it, now numbering about eighteen, and others are still arising. We have no other epidemic disease, nor have we had any recently. No other probable cause having been discovered, we desire to know whether it has been propagated by contagion.

Do the urine, and the perspiration, and the saliva, etc., as well as the excreta from the bowel of the patient according to Sir William Jenner, contain its specific poison? If they do, in what stage does it first appear, and when does it disappear? and are its poisonous properties destroyed by boiling water? Any information that you may give, and especially respecting its contagious nature, will perhaps be gratefully received by many of your readers. To invite the professional mind to repeated reflections on the character of a disease so universal and fatal, is to do no more than its importance requires. Very respectfully,

T. G. WITTEN.

TAZEWELL COURT-HOUSE, MD., Feb. 7, 1882.

[Our correspondent's case is instructive. The typhoid germs—probably contained in the excreta—admitted to the soil and ground water, became active, and hence the subsequent cases. Typhoid is a miasmatic infection, rather than a contagious disease. Some of our correspondent's inquiries cannot be answered in the present state of our knowledge. That boiling water destroys the vitality of typhoid-fever germs, seems highly probable.—ED.]

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 14, TO FEBRUARY 20, 1882.

MAUS, L. M., *Captain and Assistant Surgeon.*—The leave of absence granted him in S. O. 222, A. G. O., October 1, 1881, extended one month.—*S. O. 36, A. G. O., February 14, 1882.*

BANISTER, JOHN M., *First Lieutenant and Assistant Surgeon.*—Fort Reno, Indian Territory. The leave of absence granted him in January 1, S. O. 18, Department of the Missouri, January 24, 1882, is extended one month.—*S. O. 16, Military Division of the Missouri, February 15, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

ORIGINAL LECTURES.

PURULENT OPHTHALMIA.

A Clinical Lecture, Delivered January 24, 1882.

BY OREN D. POMEROY, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

GENTLEMEN: The disease of which I am going to speak to-day is ordinarily called purulent ophthalmia. Some authors speak of it as blennorrhœa, others as Egyptian ophthalmia, others again as military ophthalmia, and sometimes it is spoken of under the name of pyorrhœa, which name is used to designate the disease when pus is a more important constituent in the discharge than in the less dangerous varieties. It is of the same nature as catarrhal ophthalmia, it being a matter only of difference in degree between the mildest form of catarrhal conjunctivitis, and the most destructive form of blennorrhœa, or purulent ophthalmia. The disease is called purulent ophthalmia because one of its characteristic symptoms is the discharge of a considerable quantity of pus from the conjunctiva. It is one of the most dangerous diseases which affect the eye. This is owing principally to its liability to involve the corneal tissue, although it may be primarily a simple conjunctivitis. This disease differs from ordinary conjunctivitis in the fact that the ocular conjunctiva is more likely to be inflamed, and that to a greater degree than in any other form of the disease.

This affection may commence as a mild catarrhal conjunctivitis with a discharge that may be only serous, or sero-mucous, or it may contain a small quantity of pus at the outset. It is likely to develop and reach its acme in two or three days, progressing to this point much more rapidly than any other form of eye disease except diphtheritic conjunctivitis or perhaps acute glaucoma.

In one, two, or three days, the secretion will change from a thin serous, or sero-mucous, possibly containing a little pus, to the purulent form, when it shows all its characteristics. The amount of pus secreted is sometimes enormous. The redness of the conjunctiva will be much greater at the beginning than at this stage. The discharge in many cases is very much less in quantity in the early stage than afterwards. The conjunctiva may be intensely red, apparently almost dry and shining. This stage is exactly opposite to a later condition, where there is paleness of the conjunctiva, excessive discharge, and great relaxation of the parts. Photophobia and pain may or may not accompany the early stages of the disease, and is usually considered indicative of corneal complications. If there is no photophobia or pain, it has generally been considered that the cornea is free from disease. When the disease is fully developed, the discharge increases in amount, and becomes almost purulent. Do not always look for the appearance of pure pus, for if pus be mixed with tears, the latter will dissolve it in some measure, producing an appearance somewhat resembling the whey of milk, or as though oil and water had been mixed.

After two or three days, rarely in one day, the eyelids become exceedingly swollen, and they may be very red, shining, tense, and puffed out enormously; the swelling being largely a serous infiltration of the subcutaneous connective tissue. The swollen lid will naturally pit upon pressure, and thus become thinner. It enlarges in every direction, so that the upper lid will be pushed down over the lower one, overlapping it like a curtain. The lid will be so stiffened by exudation, that it will often be impossible to evert it. The conjunctival mucous membrane will exhibit the more characteristic qualities in a bad case of purulent ophthalmia. It will be enormously swollen, especially if it be the seat of true chemosis. The exudation may be of a lymphoid character. This being the case, the conjunctiva will not be as red as before, it will have a brawny appearance, and the cornea will only be visible as a cup-like depression. The retrotarsal fold will be pushed forward, and give rise to a tendency to eversion, especially of the lower lids, but sometimes also of the upper. Matters will go on in this manner for some days. The milder the case, the sooner changes for the better take place; the severer the case, the later. The signs of resolution naturally would be the diminution of swelling in the lids, subsidence of the discharge, and gradual disappearance of its purulent quality. If the swelling of the ocular conjunctiva continues for a few days, you will find, very likely, that the nutrition of the cornea is being interfered with. The first sign of this is a loss of epithelium here and there, giving the appearance of roughness to the cornea. What would be worse than this would be a little milky appearance, or slight opacity of the cornea extending in all directions, like glass that had been breathed upon. This opacity, after a little time, will result in ulcers, or, as Stelwag has said, herpetic efflorescences. This process may extend so as to involve a large portion of the cornea, and result in a complete slough; or, it may extend deeply into the cornea, perforating it, causing evacuation of aqueous, and the production of anterior synechia. This will sometimes have the appearance of a fly's head, when it receives the name of myocephalon.

The *duration* of the disease varies according to its severity and the constitutional peculiarities of the patient. From three to six weeks may be set down as the average. It frequently changes after a few weeks to the chronic form, when, as granular conjunctiva, either with or without the trachomatous condition, it may go on somewhat indefinitely.

The *causes* of this disease are the same as those of simple catarrhal ophthalmia. In the case which you have just seen down-stairs the cause was the blowing of cold air against the eye. Violent changes in temperature may produce it. If the perspiration be suddenly checked by the application of cold, the eye is likely to be involved. However, these cases are more likely to occur in warm weather. We have what are called epidemics of this disease, and they are more likely to prevail in warm weather; why they do so, I cannot tell. This disease has been called military ophthalmia, because, many times, when soldiers have been confined in barracks, and have been called out from a hot room to do duty on a cold morning, they have suffered from it. It is also called Egyptian ophthalmia, from its being produced by the reflection of light and heat from the hot sand, as well as the fact that the sand is blown into the eyes. Another cause is direct contact with a patient having the disease. If you take a little pus from an affected eye, and introduce it into that of a healthy one, it may give rise to an equally severe form of the disease, or to a milder form. This question is a little complex. At the New York Foundling Asylum I ob-

served that the same causes there would produce a mild case of catarrhal ophthalmia, and also an intense purulent ophthalmia, as well as acute trachoma, or almost any other disease of the conjunctiva. Pus, from a case of purulent ophthalmia, may produce a mild catarrhal ophthalmia, hence we must conclude that there is some peculiarity in the constitutional predisposition as an explanation of the fact. If patients are in a bad condition when poisoned, they are much more likely to be attacked by a dangerous form of inflammation. The element of struma, which you can put down as insufficient vitality and malnutrition, comes in to modify the effect of the disease. These, then, are the principal causes of purulent ophthalmia. There is, however, one other cause, that of diphtheria; for, after the diphtheritic membrane has been thrown off, the case may develop into one of purulent ophthalmia, and, in that sense, it may be considered as one of its causes.

The *diagnosis* of purulent ophthalmia is not difficult. The difference between this and other forms, you will remember, is, that a considerable amount of pus is found with this disease, while in the other forms there is little or no pus. In catarrhal conjunctivitis the discharge is mainly mucous; in purulent ophthalmia, it is more purulent. In the latter disease the discharge will sometimes cover the lid with a thin film, which has led to its being called membranous conjunctivitis. This form is easily distinguished from true diphtheria. In the former you can easily remove the membrane; but in the latter, not; it is thick, and extends into the substance of the conjunctiva; it is much more rapid in its course, and often likely to show its effects elsewhere. Swelling of the lids is quite a characteristic symptom of purulent ophthalmia, but should not be considered really diagnostic, as this is a characteristic of diphtheria. Another peculiarity of this disease worth remembering is, that at its very commencement, the ocular conjunctiva only may be principally involved. The colorless serous infiltration of the ocular conjunctiva in the early part of this disease is occasionally seen, and is of bad omen.

The *prognosis* is more unfavorable than that of any other eye disease, except, perhaps, diphtheria. This is owing to the tendency of the cornea to undergo destructive changes. Perforation may take place, and the contents of the eyeball be lost. Phthisis of the eyeball, or great shrinking of the capsule, is often a consequence of this disease. If this does not take place, we are likely to have opacity of the cornea. If some part of it is lost by ulceration, we may have anterior synechia, which may draw the iris to one side, so as to occlude the pupil. When the disease becomes very violent, we may have ophthalmitis, that is, essentially, an irido-choroiditis, and when severe, may result in phthisis of the eyeball, the choroid and iris being the principal source of the nutrition of the globe. These, then, are the principal complications to be feared in an unfavorable case.

I will go back for a moment to mention a phase of this disease. When, in its beginning, the ocular conjunctiva is principally involved, and there is considerable chemotic swelling, I think you can anticipate an unfavorable prognosis. No cornea can resist continuous swelling of the conjunctiva of the globe for more than a short time, as it interferes with its nutrition. The gravity of the case is largely dependent upon the kind of epidemic which prevails. In treating these cases in the Foundling Asylum, I met with so much success that I began to congratulate myself. But, to my astonishment, one fine summer's morning, I found several eyes nearly spoiled by perforation of the cornea; afterwards, naturally, my treatment was more cautious.

I remember a case which was under my charge a short time since, attended with but little pain, but there was a hard swelling of the ocular conjunctiva. I observed this for several days, and was fearful lest the cornea should be involved, but did not feel like resorting to heroic measures. After a few days the cornea began to be hazy at one corner; this slowly extended, and the eye was eventually spoiled (hopeless opacity of cornea, but no phthisis). One point which you should not forget is, that when a patient has had one ulcer of the cornea, do not be sure that there will be no other, for these cases relapse occasionally. At night is the time when relapses take place most readily. There may be one, two, or three relapses, which may end only by the destruction of the eye. An ulcer may perforate the cornea within a few hours, while you yet have the case under observation, and are treating it. Fortunately, this tendency to relapses only occurs in a comparatively small number of cases; these I would call *malignant*.

In early stages of this disease, the first indication for *treatment* is, the thorough cleansing of the eye. This is best done by the use of salt and water, a drachm to the pint. The eye may be washed with this solution, every two or three hours, usually as often as the secretion makes its appearance. Care should be taken not to irritate the eye by excessive handling. You may take what is called a silk sponge, or a piece of old linen saturated with salt and water; then, while an assistant gently separates the eyelids sufficiently to allow the eyeball to be exposed, the application may be effected. As the secretion is liable to be rolled up into minute masses, and even into elongated stringy particles, it will be necessary to gently wipe the part for their more thorough removal. In doing so, you should be careful not to harshly rub the conjunctiva, for fear of causing bleeding, as we are likely to have hæmorrhage induced by slight violence. If it is possible to evert the eyelid, you may do so, and frequently, in the superior cul-de-sac, minute masses of mucus, or mucopus may be found, which act as foreign bodies, and must be removed. If the disease does not promise to be of the severer variety, I would be careful, for a day or two, not to do too much to the eye. If there is considerable heat and swelling of the eyelids, it will be proper to use cold. For this purpose, dip bits of old linen into ice water, and apply them to the eye, changing them every three to five minutes; excess of water should be squeezed out of the cloth. This is the best method of applying cold, unless, indeed, you use a rubber bag containing water and pieces of ice. By the latter method, there is danger of producing an excessive degree of cold. In all cases, you should be careful not to push the cold farther than to moderately diminish the excess of heat. As soon as the lids are cool, remove the dressing, and wait awhile until reaction takes place, the object being simply to keep down the excess of heat during the inflammation. I think it a safe procedure in all these cases to use atropia. If you are fearful of irritating the conjunctiva, do not use it more than once a day, or just enough to maintain dilatation of the pupil. This will give you a diagnostic point as to whether the iris has become involved. I have been in the habit, latterly, of using a wash for purposes of disinfection. Carbolic acid, half a drachm to a drachm, to a pint of water, is as good as anything. The eye may be carefully bathed with this, three or four times a day. After a day or two, astringents may be cautiously commenced, but I would wait until the discharge has become fully developed. In the early stages there is very little discharge, and it is thin in quality. The conjunctiva is intensely red, and, perhaps, shining, a condition which would contraindicate the use of stimulants or astringents. We want to observe some relaxation before we are sure of the indication for the use of astringents, and this stage will be coincident with that of excessive discharge; that is, when the disease has reached its acme, or, perhaps, a little beyond that point.

Nitrate of silver is the most valuable remedy of the class of stimulants that can be used in this disease. As a collyria, you may use it of the strength of two grains to the ounce of water, dropped into the eye three times a day. If this is operating satisfactorily, the eye will experience a relief from its use, and the discharge will have a tendency to become somewhat thinner. Alum, a drachm to the pint, may also be used in the same manner, but it is of less value than nitrate of silver.

When the disease is fully developed, and there is great swelling of the eyelids, with chemosis of the ocular conjunctiva, producing the cupped appearance of the cornea, and accompanied by pain, the indications will be somewhat changed. While the excessive heat continues it will be indicated to use cold applications. At this stage it is nearly or quite impossible to evert the upper eyelids, unless it is done with such violence as to make it inadmissible. But excessive swelling of both the palpebral and the ocular conjunctiva is very dangerous to the integrity of the cornea, owing to the disturbance of its nutrition, consequent upon interference with the blood supply, consequent on pressure. What is the best manner of meeting these indications? In the first place I would suggest a canthotomy; that is, a division of the external canthal ligament. The incision should be carried well down to the rim of the orbit, the points of the scissors going somewhat upwards; at the same time you should be careful not to make more than a little nick in the conjunctiva. I would suggest first to make a slight incision through the whole thickness of the lid, then pass the points of the scissors outside of the conjunctiva, making a second incision, which shall extend farther. As the lid by this time will not be sufficiently cut away, you may pass the scissors between the conjunctiva and the skin, and cut away the ligament still more. For this purpose the scissors may be passed almost directly upwards, and by successive cuttings, while holding on to the lid with the fingers, you will soon find when the power of the orbicularis has been sufficiently weakened. The lids must needs be so divided as to give way under the pressure of the fingers; in other words, it must be pretty well cut off, in order to relieve this pressure upon the eyeball, which is doing so much mischief. This operation alone, I believe, has saved many corneas. I would not wait until corneal changes have taken place, for then it will be too late. If there is excessive swelling and considerable pain, and the swelling remains for two or three days, without any sensible subsidence, shall we scarify the conjunctiva? My present impression is that the feeling of ophthalmic surgeons generally is not to scarify as much as formerly. Should you, however, wish to adopt this method, you may evert the eyelid, and, by gentle strokes, with a sharp instrument, scarify the palpebral conjunctiva sufficiently to produce considerable bleeding. In scarifying the ocular conjunctiva I would use a little more care, the incisions should pass from near the cornea outward, in a radiating direction, otherwise too many vessels will be divided and the nutrition of the cornea jeopardized. If there is ulceration of the cornea, or opacity anywhere, will you do a paracentesis? Many authors are opposed to this operation in the acute stage. I am, on the whole, in favor of doing it in properly selected cases. The indications for operation would be the continuance of a considerable degree of pain, with commencing corneal changes, and increased tension of the eyeball (which you will find difficult to determine, as the swelling of the lids disturbs very much our judgment in this matter). I remember distinctly, some years since, an epidemic which occurred in the New York Foundling Asylum, of this city, in which, before my attention had been fully attracted to the severity of the epidemic, several corneas became perforated. After this I watched the cases with considerable care, and when a cornea showed a loss of any epithelium or any cloudiness, an operation was at once performed, and after that I do not remember to have observed the perforation of a single cornea. Paracentesis may be done every day or two, if necessary, but do not think that it will save the cornea after it has become considerably infiltrated. Certainly, if the cornea becomes cloudy *early in the disease*, you will despair of saving it, whatever you do. On the contrary, when it occurs during the subsidence of the disease, you may then expect better results from paracentesis. Together with paracentesis I would make a pretty vigorous exhibition of atropia, using a four-grain solution three or four times a day. If there are paroxysms of pain the atropia may be used every fifteen minutes until it has subsided, if this is possible. It will be proper, if our cold and atropia does not relieve the pain, to administer some form of an opiate. However, in this stage, when the corneal changes show signs of taking place, hot applications are acceptable, and may be used on the theory that heat is stimulating to the eyeball, and assists in maintaining its vitality. The hot applications may be made in the following manner: Small bits of rags, dipped in water, as hot as the assistant can bear, are wrung out into the eye. This plan, though very serviceable, is not quite so practicable as the dipping of rags into very hot water and laying upon the eyes, and changing them frequently. A small, thin, and light rubber bag, containing hot water, is a good method of applying heat, in the same way that it was used in applying cold. In this stage it is quite proper, in making applications, to continue to use those which afford most relief to the patient, barring one exception, hot applications. If the latter are applied continuously, for some time, they will act like a poultice, and produce a maceration or softening of the tissues, which may be accompanied by relief of pain, but are likely to facilitate the disorganizing processes.

If the cornea breaks down for a considerable portion of its area, the eyeball is destroyed. The lens is likely to be extruded, or if not, the cicatrix forming will cover so large a portion of the cornea as to make any future operation for visual purposes impossible. Moreover, it may develop into a staphylomatous protrusion which may give rise to a good deal of trouble. Naturally, if the lens is extruded with discharge of vitreous humor, or if there is panophthalmitis, you can only expect atrophy of the eyeball—phthisis bulbii. Although the disease does not always involve the second eye, it is liable to do so on account of the poisonous matter passing from the bad to the good eye. Hence it will often be proper to seal up the unaffected eye. This should be done in the early stages of the disease, before the formation of pus has shown itself to any extent. For this purpose, you may take a piece of absorbent cotton, and apply it to the eye; this is covered with diachylon plaster. A coating of collodion is now applied over the plaster so as to secure it to the skin, and hermetically seal the eye. A second coat of collodion is passed over the whole, and the dressing is complete. This may be removed daily, and the eye carefully examined. It will be well to wash the closed eyelids with carbolic acid, so as to destroy any poisonous material found on them. This is about the ordinary termination of blennorrhœa. It will either be soon well, or will go on into a chronic state of inflammation, assuming a condition known as chronic granular conjunctivitis, or even true trachoma. These conditions will require appropriate treatment. During the period of discharge and swelling of the conjunctiva, after it becomes possible to evert the lid, nitrate of silver may be applied to the conjunctival lining. From 40 to a 100 gr. solution should be used, sufficiently strong

to make an impression on the lid. If it is doing well, the discharge will become thinner and the swelling diminish; photophobia should not result from the application, and to protect the cornea, it should be carefully washed off with salt and water. In a later stage alum or cup. sulph. in substance may be substituted. As long as the good effect of one application continues do not repeat it, but even strong arg. nit. may sometimes be repeated daily, for two or three weeks. Do not continue one remedy after it seems to disagree with the patient, but change to another.

ORIGINAL ARTICLES.

THE VARIOLOUS DISEASES:

VARIOLA—SMALL-POX; VARIOLOID, AND VACCINIA.

History, Etiology, Clinical and Pathological Characteristics, etc.

BY ROBERTS BARTHOLOW, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

History.—The first accurate description of variola to be found in medical literature is that of Rhazes, an Arabian physician, who lived in Bagdad about the beginning of the tenth century. He maintains that Galen was acquainted with the disease, but he bases this statement on an erroneous translation. The writings of Rhazes on small-pox and measles have been translated for the Sydenham Society, by Dr. Greenhill,[1] and may, even now, be read with advantage. There was no word in the Greek or Latin languages for this disease. The term *variola* was coined out of the Latin *varus*, a pimple; or *varius*, spotted; and the first appearance of this word in literature was in the year 961. *Poc*, as the word was written originally, is Saxon, and signifies a bag or pouch; but it has since been written *pock*, or *pox*. In the fifteenth century syphilis appeared, and then *small* was added to *pox*, to distinguish it from the *big-pox*, or syphilis. The earliest reference to a disease, agreeing in its clinical features with small-pox, was in the sixth century, during which an epidemic of this malady appeared in Arabia and Egypt. The extraordinary social and political convulsions which attended the rising of Mohammedanism served to spread the disease through the surrounding nations. After Columbus, America was visited, and small-pox and gunpowder came into the continent with Christianity and civilization. The followers of Cortes introduced the disease into Mexico, and more than three millions of the people perished in one epidemic. After its first appearance in Europe, successive epidemics carried off vast numbers. In the eighteenth century thirty thousand died annually from small-pox in France, and about the same proportionate mortality obtained in Prussia and other European States. So universal was the prevalence of the infection, and so remote the probabilities of escape, that it became a proverb—"from small-pox and love few remain free." (Curschmann). Before the discovery of the protective power of vaccination, this disease, for several centuries, had been the terror of mankind. It was to be feared not only because of the immediate mortality, but the deformities and impairment of function which resulted in a considerable portion of the cases. The present epidemic, although sufficiently grave to cause uneasiness, does not compare in violence to the great epidemics which decimated the countries visited by them. In place of the terror, which formerly seized mankind on the approach of a small-pox epidemic, there is now a sense of security and protection felt by all those who have the wisdom to avail themselves of the immunity secured by vaccination.

Causation.—There is now no difference of opinion in regard to the existence of a contagious principle—a peculiar poison, whether an unorganized ferment or a minute organism—which, reaching the person of a susceptible subject, undergoes a process of multiplication, and develops the morbid complexus of variola. There can be no doubt, also, that the poison exists in the pus of the pustules in its highest activity. It would be more correct, probably, to say that the virus is most infective at that point in the development of the pustules when the clear fluid of the vesicles begins to grow turbid—when the vesicles are changing to pustules. There is, probably, no part of the body which may not impart infection. Emanations from the patient—perspiration and breath—contain the poison, but its activity is in inverse ratio to the distance. The stories told of contagion happening to persons who passed by the house or called at the door of a variolous subject, are largely apochryphal. Not less doubtful is that assumed keenness of scent possessed by some physicians who affect to smell small-pox from the street when the patient is in a remote upper room. The odor of a small-pox patient is peculiar, and some physicians have, it must be admitted, an astonishing acuteness in distinguishing it, when in the *immediate neighborhood* of the person affected. It is supposed by some that the odor is closely connected with the *materies morbi;* others maintain, and with more reason, that the odor is the product of the putrefaction of the pus and exhalations from the body, which have soaked into the bedding and clothing.

The susceptibility to the contagion of small-pox varies in different individuals, and is probably not wanting to any one. Negroes possess a special aptitude. The period in life of the maximum susceptibility is from the first to the fortieth year, but it may happen at any period. The disease occurs even in intra-uterine life, but it is exceedingly rare. A healthy mother has given birth to a child with small-pox, but it is more usual for the infection to take place from the mother, who is also affected with the disease, although it may be in an abortive form, which was not correctly diagnosticated.

The susceptibility to variola is usually destroyed by having an attack, but there are some examples of two, even three, seizures in the same person, but they are comparatively rare. Successful vaccination is not inferior to variola in the power to remove the susceptibility, but the questions connected with vaccinia are reserved for future consideration. The virus is conveyed by articles of clothing, paper

[1] A Treatise on the Small-pox and Measles, by Abeé Beer Mohammed Hu Zacarîyá Ar Rázî (commonly called Rhazes). London, 1848.

money, which were on or about the person during the disease. It may preserve its activity for a long time—for months, even years—when not freely exposed to the air. Those who handle rags are, as all the world knows, much exposed to contagion, and many are attacked. There can be little doubt that paper money is a frequent medium of communicating the disease, for few of those affected possess no specimens of the paper currency. At what period in the course of the disease the chances of contagion are most numerous, cannot be accurately stated. It is reasonable to suppose that the poison is most intense when the disease is at the maximum, but it is certain that infection may occur at any time, even during the period of incubation. The susceptibility of those exposed has a large influence on the result. Very singular experiences have been narrated in respect to the sensations felt at the time of exposure to small-pox contagium. A disagreeable and sickening odor, faintness, giddiness, and fright, have been experienced at the moment of contact with the virus. But such sensations are rare; usually nothing is felt or suspected at the time. A certain period elapses from the moment of acquiring contagion until the symptoms begin. This period is entitled

The Incubation.—Unconsciously to the affected person, in a majority of the cases, the poison works "an infection of the blood," multiplies or develops, until solids and fluids alike receive the impress of the taint. In a minority, the period of incubation is accompanied by a general *malaise*, by languor, mental and physical, restless nights, feeble digestion, and other evidences of illness. The duration of the period of incubation is about fourteen days for small-pox, but it is not a fixed period. It ranges from ten to fourteen days in most cases, but may be as short a time as five days. Some individuals appear to have a natural proclivity to small-pox, and in them the variolous germ affects all parts with great promptitude. The more intense the poison, probably, the shorter the period of incubation. A distinction has been made between the *incubation* and *invasion* period, the former extending from the reception of the poison to the onset of symptoms, and the latter from the initial chill to the appearance of the eruption.

Symptoms.—The invasion period begins when the incubation ends. From the first disturbance—the chill—to the appearance of the eruption, is an important period, sometimes called the *prodromic*, sometimes the *initial*, but which we prefer to designate, as the older writers have done, the *invasion period.* The chill with which the disturbance begins may be a violent rigor, or consist of a state of chilliness lasting several hours. The fever rises promptly, on the first day even, to 103° or 104° Fahr., and the pulse corresponds, attaining to 110 or to 140 per minute. Not to occupy space with minute details, it suffices to say that the systemic state is that of a high fever. There are, however, certain peculiarities of the invasion stage of small-pox which demand the most careful consideration. An intense, splitting headache, an equally severe backache, and rending, tearing pains in the extremities, especially about the joints, characterize the onset, and persist during the whole of this period. There may be violent delirium, and in children, convulsions. On or about the second day, but very irregularly in point of time, the peculiar *rashes* or eruptions of the invasion stage, make their appearance. These require attentive examination the more since they give rise to errors of diagnosis. Nothing is more common than to hear in the reports of society meetings, examples of the concurrent appearance and development of scarlatina or measles with variola, when, indeed, they were simply examples of these invasion rashes. They are rather exceptional than regular; are common in some epidemics, but are unknown in others. They have the aspect of a scarlatina or measles eruption, or they are petechial or hæmorrhagic, and sometimes these characteristics are combined, as petechiæ overlying the scarlatina exanthem. A further peculiarity of these invasian rashes is their arrangement. The erythematous are apt to be diffused over the body or localized to the anterior or extensor surface of the extremities and extend along in the form of a streak. On the other hand, the petechial rash is collected in certain regions forming triangles, and named from the expert who defined them, "Simon's triangles." The *crural triangle* is the eruption collected on the lower abdomen, the genitals, and the inner surface of the thighs, and the *brachial triangle* is formed by the eruption on the pectoralis, the axilla, and the inner face of the arm. An important aid to diagnosis is thus afforded us amidst the perplexing doubts which must arise during the invasion stage.

The duration of these rashes is variable; the erythematous disappearing in from twelve to twenty-four hours, and the petechial lasting several days.

The invasion stage exhibits other peculiarities. In a few instances, fortunately, the poison acts with deadly intensity; the blood is quickly decomposed, and death ensues before the eruption can appear. The disease, beginning in the usual way, but violently, is characterized by the occurrence of great prostration, by the appearance of an erythema on the body and extremities, and by subcutaneous hæmorrhages. Petechiæ and vibices flow into the erythema, and, whilst discrete on the extremities, form large, irregular figures on the abdomen and chest. Hæmorrhages take place under the skin of the eyelids; the conjunctivæ are intensely infected, and the face is swollen; diphtheritic exudations form in the fauces; albumen appears in the urine; hæmorrhages occur from the mucous surfaces generally, and the body emits a horrible fœtor, and has a dark-grayish or black tint. Such cases terminate in a few days, rarely continuing beyond the sixth day. This form of the disease owes its grave character to the hæmorrhagic diathesis—to the dissolution of the blood—and is, hence, styled *purpura variolosa.*

The Eruption Stage.—At, or soon after, the third exacerbation of the invasion fever, the eruption begins to appear. With the coming out of the eruption a great change occurs in the other symptoms. In many cases—especially the milder, discrete ones—

the temperature falls in a few hours to normal, or even below. In other cases, the fever remains at the maximum, or rises even higher, for twelve to eighteen hours after the eruption begins to show itself, when a gradual decline to the normal occurs in the less severe cases. In the severe corymbic, and in the confluent forms, however, and in the hæmorrhagic, the defervescence is slight, or there may be none. With the appearance of the eruption, also, there is a remarkable improvement in the condition of the patient. The severe pains in the head, back, and limbs cease; if vomiting has occurred, it is arrested; if there has been delirium, the mind clears.

The eruption appears first on the forehead and hairy scalp, and spreads thence over the body within twenty-four hours. The whole number of papules are out within two days. When each papule is perfectly distinct, and separated by a district of healthy skin from all surrounding papules, the eruption is said to be *discrete;* when the papules are so thickly placed that, although each is distinct, they come into contact at their border, the eruption is said to be *coherent*, and when they are merged together without distinction, *confluent.*

The eruption forms around a hair follicle or the orifice of a sebaceous or sudoriparous gland. At its first appearance, to the touch it seems like a bird-shot lodged in the skin, so well defined and hard is it. On the second day the eruption has a distinctly papular character, is larger and redder in color. On the third day of its existence the papule is still further enlarged; it now contains a pellucid fluid, which, for a day or two increases in quantity, becoming first cloudy then distinctly purulent. As the vesicle thus changes in the character of its contents, it also alters its form somewhat; a depression or umbilication appears in the centre, corresponding to the opening of a follicle or gland in the skin, but this is not invariable, for the umbilication still is present in the pustules formed elsewhere. Auspitz and Basch[1] held that the central depression is produced by the more rapid development of the periphery, and consequently greater accumulation of material in this part of the pustule.

The anatomical structure of the pock is an important and interesting part of the subject, for the nature of the pustule is the same whether the disease be small-pox, varioloid, or vaccinia. The first point to note is, that one incision, unless it include the whole circumference of the pock, will not evacuate the lymph. There are septa, which divide the pustule, and in the interstices of which the lymph is enclosed. The pock has, in fact, a cellular structure, a network of an epithelial character, which is well depicted in (Tafel vi., Fig. 1) the plate accompanying Auspitz and Basch's article, and reproduced by Curschmann.[2]

In about six days after the first appearance of the eruption, the pock is fully developed. If undisturbed in its development, it is then hemispherical in shape, with bevelled margins, and the central cup has filled up as the purulent contents have accumulated, so that the top is rounded off or *acuminated.* The previously clear lymph is now filled with pus corpuscles, and hence, the contents of a matured pock are purulent. The inflammation in the skin is not strictly limited to the site of the eruption. On the fourth day an inflammatory circle surrounds each pustule, and is known as the *areola.* It deepens in color and widens at the circumference, as the maturation of the pustule proceeds. Within this area the skin is hard and brawny, and more or less swollen, consequently when the pustules are thickly set there may be great deformity—as about the face—the features becoming indistinguishable in coherent and confluent cases.

The *maturation* of the pustules is no sooner completed than a process of drying and the formation of a scab begins. About the seventh, eighth, or ninth day of the eruption a viscid material exudes from the pustules, quickly dries into a yellow waxy coating; the contents also solidify, and thus a scab is formed. As the drying proceeds from the centre, the umbilication again appears. The formation of typical scabs may be prevented by rupture and escape of the contained pus and by confluence. When the crusts are detached, the place which they occupied has a dark, brownish tint, which finally disappears, the scar becoming paler ultimately than the surrounding skin. As very considerable sloughing may occur in some situations, especially about the face, very unsightly deformities will result.

The eruption is not limited to the external integument, but appears, also, on the mucous membrane lining canals opening externally, especially on the lips, pharynx, tonsils, and palate. Invasion of the larynx will be shown by the change in the voice, and the nasal passages will be obstructed when the pustules form in them. The vagina, urethra, and rectum are comparatively exempt, although not entirely so, the pustules being few in number and widely distributed.

The order in which the maturation and exsiccation of the pustules takes place, is that of the original efflorescence. The parts on which the papules first form are, also, the first to go through the successive steps in development up to the final desiccation and scabbing. Those parts occupied by the invasion rashes may be free from the eruption, but the same parts may be exempt when there were no preliminary eruptions.

We are now prepared to consider the various phenomena attendant on the development of the pustules—their maturation, desiccation, and cicatrization.

It is not difficult to conceive that such an extensive inflammation of the skin—such wide-spread suppuration—would induce the most severe disturbances.

Fever of Maturation.—When the lymph becomes purulent, the fever rises again into prominence. With the appearance of the eruption, the fever in discrete cases falls to normal; in the more severe coherent cases, declines notably, and in the confluent cases, merely lessens a little; but when suppuration occurs, the temperature rises in correspondence with the extent of pus production. The maturation fever

[1] Virchow's Archiv. Band xxviii., p. 337. Untersuchungen zur Anatomie des Blatternprozesses.

[2] Ziemssen's Cyclopædia, Vol. ii., p. 383.

is of the quotidian, remittent type, and the maximum heat ranges from 101° to 104° Fahr. The pulse has a frequency in conformity to the range of temperature, and fluctuates between 90 and 160, according to the age and sensitiveness of the subject. Various circumstances contribute to the disturbance. The burning in the skin, the soreness of the tongue and throat, the aching of the back and limbs, the headache and the wakefulness, make up a complexus of severe symptoms. It is not surprising that delirium should occur in many cases; sometimes it is of the ferocious kind, the patient becoming dangerous, jumping from the window and escaping into the street; sometimes it is of the low, muttering variety, and in the subject of chronic alcoholism it readily takes on the characteristics of delirium tremens. From the eighth to the twelfth day of the disease the fever of maturation is at its maximum. With the process of desiccation, it declines, by slow stages, the daily excursions of the temperature growing shorter, until, with cicatrization, the normal is attained.

With the drying of the crusts, usually, considerable itching is experienced, and injury is done by scratching if any additional inflammation is thereby induced, but not otherwise. At the site of the pustule, after the scab is detached, more or less pigment deposit gives a brownish appearance to the cicatrix. After some weeks these disappear, and gradually the scar assumes the well-known and characteristic appearance. The skin may be damaged in other ways. The hair follicles may be destroyed and the hair fail to be restored, but such a disastrous result is unusual. The nails, another appendage of the skin, may also be destroyed, but this rarely happens.

Course, Duration, and Termination of Discrete or Coherent Variola.—From the initial chill to the appearance of the eruption, is the invasion, initial, or prodromic period. The eruption comes out at or after the third exacerbation of the fever—from forty-eight to seventy-two hours after the rigor, says Gregory. The process of maturation of the pustules occupies from five to ten days, the average being about seven days. Drying, scabbing, cicatrization, and the falling off of the scabs, will occupy some days longer. About three weeks will thus be occupied in an uncomplicated case with the evolution, progress, and decline of the disease. Convalescence will be more or less protracted, according to the severity of individual cases.

The question of termination is so largely affected by the form of the disease and by the protective power of vaccination, that no general statement can afford any instruction. The period of the disease at which a fatal termination is most to be expected is, however, an affair of some moment. We find in a table of 163 cases of death given by Gregory[1] that the largest number of deaths occurred on the eighth day, the eleventh day coming second, and the ninth day, third, in the order of relative frequency.

So much depends, in the consideration of the variola question, on the number of pustules, and on a certain unexplained virulence of the poison, that we must not fail to pursue these topics. The former must be studied as it occurs in *variola confluens* on the one hand, and in *varioloid* in the other; the latter presents itself to us in the *hæmorrhagic variola.*

[1] The Eruptive Fevers, op. cit., p. 75.

VARIOLA CONFLUENS.

In this form of the disease we find the variolous poison most active and deadly. This characteristic manifests itself from the beginning of symptoms. It is probable, also, that the period of incubation is shorter. The initial chill is most violent, the headache and backache intolerable, and the limbs are torn with rending joint pains. The eruption struggles for an early appearance, and the fever is high, with feeble remissions. The eruption appears earlier than in ordinary cases, and it comes out almost simultaneously over the whole body. At their first appearance the papules are so closely placed on the face and hands that no part of the skin seems untouched, and on the second day are already uniting in large, flat vesicles. The skin by this time is much swollen, deeply red, and covered with patches of the confluent eruption; on the third day elevated into large, flat, sero-purulent bullæ. The face is especially the seat of the most complete confluence of the eruption, which here forms a large pustule, covering the whole and completely obscuring the features, which are further blended together without distinction by the enormous swelling. Elsewhere the eruption is closely placed, even coherent, but not confluent except over small areas.

The mucous membrane of the mouth, pharynx, larynx, and nose, is also the seat of a confluent eruption. Extensive diphtheritic exudations cover the tonsils, palate, and cheeks, and extend into the nose; the tongue swells enormously, and protrudes between the teeth, covered with large bullæ; the larynx is not only attacked by the eruption, but the cartilages are inflamed and necrosis ensues; œdema of the glottis occurs; a horrible fetor is emitted from the nose and throat; the submaxillary, sublingual, and deep cervical lymphatics are greatly swollen, impeding the return of blood from the head; swallowing is excessively difficult or impossible; respiration is labored and shallow, and the conjunctivæ covered with pustules; the cornea may be perforated.

The fever of the invasion stage ranges from 104° to 108°, even to 110° Fahr. When the eruption appears the temperature falls but a little, and as the pustules mature, rises again to the former point, or even higher. The other general symptoms are correspondingly severe; the pulse is small, rapid, and feeble; there are severe, often uncontrollable vomitings, and an exhausting diarrhœa may set in. Stupor and coma, or violent delirium, may occur in different cases; or, after active delirium, coma may supervene. In some cases the mind is perfectly clear until near the close. Albumen is present in the urine in a considerable proportion of cases.

Various complications arise in the course of confluent small-pox; intercurrent diseases, as endocarditis, pericarditis, pleurisy, and pneumonia, abscesses, sloughs, and gangrene, and cerebral de-

rangements from the pressure on the jugulars, and from albuminuria.

Course, Duration, and Termination of Confluent Variola.—As already indicated this form of variola is more rapid in its course than the ordinary form. Owing to the concentration and activity of the poison, the invasion fever ranges at the maximum (105° to 110° Fahr.), the eruption anticipates, and the temperatures lessens but slightly when the exanthem appears to rise soon to the maximum again. In the most severe cases the eruption scarcely appears, the skin is dusky red, and so greatly swollen that the features cannot be distinguished, the circulation is very feeble, the urine scanty or suppressed, and the mind wanders in a low delirium. Death ensues in such cases, as in those of purpura variolosa, from the profound changes in the blood, before the characteristic evolution of the disease can take place.

In other cases the termination occurs by exhaustion from the extraordinary range of temperature during the development of the eruption. With maturation and the extensive suppuration, pyæmia develops in some cases, and proves fatal. Others again are carried off, during the eruptive stage, by an acute œdema of the glottis. Sloughing and gangrene of the fauces, with diphtheritic exudations, swelling and black discoloration of the tongue, with deep-seated phlegmon of the organ, and a profound adynamia of the general system, are symptoms to which the older writers applied the not inapt term "black small-pox."

If the patient survive the various accidents and complications, he may succumb to the exhausting discharges, and to the abscesses and sloughs that follow in their wake. Although the mortality is large, death is by no means invariable. When recovery ensues, convalescence is necessarily tedious. Extensive losses of substance must be repaired, and in a large proportion of cases, permanent deformity, to a greater or less extent results from destruction of the cartilages of the nose, larynx, perforations of the cornea, and of the drum-head, etc.

VARIOLOID.

As variola confluens represents one extreme, so varioloid is the type of the other extreme. That varioloid is a distinct disease is a popular but an unfounded medical opinion. There is no true distinction between variola, varioloid, and vaccinia, for, as we will see, the anatomical structure of the pock is the same in each.

Varioloid is simply small-pox, modified by some circumstances, chiefly by the process of vaccination. Before the discovery of vaccination, however, there were occasionally encountered cases characterized by the mildness of the symptoms and the irregularity of their behavior. It is supposed that in such persons an insusceptibility to the variolous poison existed. At the present time, however, the chief cause of the extraordinary mildness and irregularities of many cases is the protective influence of vaccination.

The invasion stage of varioloid varies greatly in violence, but its severity is no measure of the gravity of the case to follow. The invasion rash—*erythema*—is of common occurrence in varioloid. As the regular eruption—it will be remembered—does not, as a rule, appear on those parts occupied by the invasion rashes, it follows that the more extensive the invasion exanthem, the less the number of pocks to appear. Whilst it is true that the erythematous eruptions of the invasion stage belong to varioloid, the petechial belong to variola. It seems to be true, further, that the better defined the erythematous rashes of the invasion stage of varioloid are, the milder the disease. A careful study of the eruptions of the invasion or prodromic stage is, therefore, necessary to make them available as accurate prognostic and diagnostic guides.

The invasion stage of varioloid may be shorter, but is more often longer than that of variola—often four rather than three days. The fever may be very considerable and there may be much headache and backache, but when the eruption appears, a rapid defervescence takes place to the normal temperature or even below it, and at the same time all of the pains and other distresses cease. The fever does not again appear, except at the period of suppuration, when it occurs in some cases briefly.

The eruption of varioloid does not pursue any regular order; sometimes beginning on the body, sometimes on the face, and now it spreads regularly over the whole surface; again, it appears simultaneously on all parts. The eruption itself exhibits similar peculiarities. The pock has the same structure as that of variola, and sometimes extends as deeply into the true skin, and leaves a distinct cicatrix; but more frequently it does not fully develop, or passes through the several stages of development imperfectly. The eruption of varioloid, when it goes through all the stages, begins as a small papule, and, in twelve to eighteen hours, assumes a vesicular appearance, sometimes with, often without, the umbilication. On the third or fourth day, the clear fluid of the vesicle is becoming purulent, and it is surrounded with an areola, but there is no swelling of the skin. The pustules dry by the fifth to the seventh day, usually without bursting; and the scab falls off very soon, leaving a slightly colored spot, which soon disappears. The number of pustules varies greatly, and, of course, according to the number of them is the severity of the disease.

HÆMORRHAGIC VARIOLA.

When a purpuric condition of the blood is associated with variola in its invasion or prodromic stage, we have that condition which has been entitled *purpura variolosa*. The variolous poison is then in its highest degree of activity. Before the exanthem can develop, the patient is moribund. *Hæmorrhagic variola*, however, is that form of the malady in which hæmorrhage occurs during the stage of pustulation. The debilitated convalescents from other diseases, and women in childbed, are especially liable to this form. It is characterized by the severity of the pains, the range of temperature, but especially by the occurrence of hæmorrhages into the pustules at various stages in their development, and from the free mucous surfaces. The hæmorrhage may occur in the papules before developing their vesic-

ular character, or in the vesicles on forming, or in the pustules after they are fully formed. The order in which the eruption is affected by the hæmorrhage varies, most frequently beginning on the inferior extremities. Sometimes a part of the body—it may be a very small part—is affected; sometimes every pustule is hæmorrhagic. The hæmorrhage occurs by degrees. Not only the pustules, but the skin generally, between the pustules contains ecchymoses and petechiæ. Large livid spots appear on the mucous membrane of the mouth and pharynx; extensive diphtheritic exudations form on the tonsils, palate, and cheeks, and the breath emits a most offensive odor. Hæmorrhages also take place from the nose, intestines, kidneys, and pregnant women abort with frightful hæmorrhage.

As regards the violence of the symptoms and the mortality from this disease, much depends on the extent of the hæmorrhages. If but a few pustules are hæmorrhagic the symptoms will not be so grave, and recovery may result. As a rule, however, this form of the disease is the most formidable, next to its cogener, purpura variolosa. The prognosis will be governed by the extent of the hæmorrhages, and by the consequent state of the vital powers. The more intense the fever, the more grave the case unless in those examples of low temperature and high pulse-rate due to hæmorrhage.

Vaccinia.

The vaccine disease occurs in the cow and horse, certainly; and probably, also, in other animals. Man is brought within its influence only by inoculation. It is a vesicular disease, specific in character, and has its seat on the teats and udder of the cow, especially of the milch cow. After a period of incubation, from three to eight days in duration, the udder appears hot and somewhat swollen, and papules come out on the udder at the base of the teats, and on the teats themselves. By the fourth day each papule has become a vesicle, and is distinctly umbilicated. The number of vesicles varies from one or two to ten or twenty, and in size they range from that of a large pin's head to a dime, the usual size being that of a pea. When allowed to develop without any obstruction, and not too closely placed, they are circular in shape; have a whitish, glistening aspect; and contain a transparent, viscid lymph. Around them is an areola, and the subjacent skin is hard and brawny. By the tenth or eleventh day the pustule is fully formed, the central depression has disappeared, the surface is conical and globular, and a quantity of yellowish lymph flows out on rupture. By the twelfth day desiccation has begun, and is completed by the fourteenth day, when the crusts are fully formed. The crusts are now of a dark mahogany color, and are detached about the twentieth to the twenty-third day. The anatomical structure of the vaccine pustule is the same as that of variola; it has the same cellular arrangement, the same umbilication, the same conoidal shape when the process of maturation is complete, and the scab has the same color and form when the separation finally takes place.

The vaccine disease may be artificially produced in the cow by inoculation, with lymph from other cows having the natural vaccinia, with humanized lymph, and with the matter of human variola. There seems to be no difference in the structure of the resulting pustule. The horse is also the subject of vaccine disease, which has all the characteristics of the same disease in the cow, and may be readily transferred to and developed in the latter animal.

What is the origin of the native vaccine disease? That it is the variolous infection which has been transferred to the cow in the process of milking, there can be no doubt. This fact was established as early as three years after Jenner's discovery, by Gassner, of Gänsburg.[1] It is true it is not always easy to effect the inoculation of cows with small-pox, but it can be done if proper attention be given to the details, and the resulting pustules have all the characteristics of vaccinia, produce the same results in man, and are equally protective against variola. The almost universal practice of vaccination must necessarily greatly reduce the number of cases of infection by this source. Vaccinia may, however, be transferred by the hands of milkers, and this is now the chief source of the natural disease. It is only at rare intervals, however, that cases of this kind are discovered. They have been a few times discovered in this country, but much of the virus used by American physicians had its origin in the Beaugeancy stock of France. Recently a case of spontaneous cow-pox has been observed by Dr. Landeau at Epines, France, and a number of heifers have been inoculated with success.[2] Cases of this kind should be observed with great care, and utilized for the production of the best stock.

There are but two methods of propagating the vaccine disease in cows for commercial purposes that should be tolerated. One is inoculation with variolous poison, and the utilization of the resulting lymph for the production of an abundant supply, by cultivation in carefully selected heifers. Against this method for producing genuine vaccinia has been urged the difficulty of inducing the disease. The highest authority on this subject, Mr. Ceely, of Aylesbury, England, has succeeded in inoculations of variolous lymph, and has produced therefrom a stock of vaccine which has been used in a large number of cases, and which has been proved to exert so perfect a protection that subsequent inoculation of variola lymph was without effect. The same results have been obtained by Badcock in England, and by Drs. Adams and Putnam, of Boston.[3] In Russia, Italy, France, and other countries, even in Egypt, this method has been successfully pursued.

The other method for the production of bovine virus, is the vaccination of carefully selected heifers with the lymph of the natural disease. It is probable that the proprietors of "vaccine farms," some of them, at least, use humanized lymph to procure the commercial "bovine virus" (retro-vaccination). Seaton says that this bovine virus "takes" more readily than the original vaccine lymph (bovine),

[1] Seaton's Handbook of Vaccination, Amer. edit., p. 57.
[2] Journal de Thérapeutique, No. 2, 1882, p. 63.
[3] Seaton, op. cit., p. 60–62.

but less kindly than the humanized, and that "papulation is usually retarded, the vesicles are often smaller, and the disease not really so well developed as by the stock from which the lymph was derived."

Has the lymph of the original Jennerian stock degenerated? Jenner maintained that if proper care was exercised in the preservation of the lymph, in inserting it in suitable subjects, its quality must always be maintained at the original standard. The stock now used at the National Vaccine Establishment (London), is the descendant of that supplied by Jenner, and preserves all of its original protective influence, and corresponds exactly in development to the vesicles figured by Jenner in his original work (Seaton). If it has thus preserved its proper characteristics and its activity for more than eighty years, it is not probable that it will ever change. Unfortunately for the good name of the Jennerian lymph—the humanized virus—so little care has been exercised in the preservation of lymph, and in the selecting of subjects for its propagation, that much spurious vaccine has been produced, and used with the confidence only appropriate to the genuine virus. It is not surprising that failure to protect should be alleged against such imperfect virus.

Bovine vs. *Humanized Virus.*—The question of the employment of humanized or bovine virus involves various considerations. It may be considered settled that genuine humanized lymph descended from the original stock of Jenner, retains the original characteristics as respects manner of development, and possesses the original protective power. There are several vaccine stations in England where this lymph is still used, and it is found to be equal in all respects to the original, and affords the same degree of protection. This fact established, it would seem then to be only necessary to employ such virus. Unfortunately many conditions have occurred to vitiate this matter. It is becoming increasingly difficult to procure unquestionable specimens from the original source. Furthermore, amongst the millions of examples of safe and successful vaccination, there have occurred some few instances of vaccinal syphilis. Probably not more than ten cases of such infection in regard to which no doubt can exist have ever been observed.[1] Other maladies have been reported thus caused, and various eruptions attributed to vaccination, but without reason. The eruptions and other affections due to vaccination will be alluded to further on. If the process of vaccination and securing of lymph were rightly performed, no contamination could occur. Unfortunately the blood and other fluids of syphilitic subjects are sometimes carelessly mixed with the vaccine lymph. The possibility of such contamination has awakened a widespread distrust of humanized virus, and so ready are parents now to attribute any kind of subsequent mischief or disease to the vaccine virus, that if anything occurs at any period afterwards, it is referred to the vaccination.

[1] The cases reported by Mr. Hutchinson have best withstood the criticisms justly made on all examples of vaccinal syphilis.

In consequence of the deterioration of the Jennerian lymph, by careless treatment, and the possibility of contamination by syphilis, bovine virus has come to be largely substituted. This substitution may, or may not be wise. It would be unnecessary if genuine Jennerian lymph were available; it may be desirable if the original vaccine disease furnish the lymph, whether occurring spontaneously or purposely by the inoculation of the matter of variola. It is questionable if bovine virus, from retro-vaccination, is the only source of supply.

There are certain peculiarities in the action of the original bovine virus, as compared with the humanized. It acts with less certainty. From the vast number of statistics on this point, we select those of Dr. Gibert, of Havre, who gives the results of vaccinations and revaccinations as practised at the Dispensary for Infants' Diseases with bovine virus from Milan, and from the French Society of Hygiene, at Paris, and with Jennerian vaccine.[1] Of infants, vaccinations with

	Cases.	Successful.	Unsuccessful.
Milan, virus of,	104	89	15
Paris, "	37	22	15
Humanized, "	64	56	9

Of revaccinations in adults with

	Cases.	Successful.	Unsuccessful.
Milan, virus of,	625	352	262
Paris, "	76	32	44
Humanized, "	27	19	9

These statistics correspond to the general experience of the most competent authorities. Bovine virus acts more powerfully, as respects the local phenomena and constitutional symptoms, and various papular and vesicular eruptions appear on various parts of the body more frequently than when the humanized virus is used. The crust tardily desiccates, and is detached comparatively late, leaving a deep, foveated cicatrix. The harshness and violence of action of the bovine virus declines by transmission through two or three subjects, and the vesicle improves in size and perfection of detail. Obviously, then, *the typical lymph is that obtained from virus three or four degrees removed from the original natural cow-pox, and transmitted through healthy infants.* It is admitted by all who possess any accurate knowledge of the subject, that humanization improves the original vaccine lymph. Only doubt intervenes in respect to humanized lymph, which has been transmitted through so many, that a lack of care in the selection of virus, and of the subjects receiving, may have vitiated the product.

Vaccination and Attendant Phenomena.—To offer observations on the subject of the manner of vaccinating, may seem a superfluity. So much carelessness, however, is permitted, and the consequences of carelessness are so tremendous, that we may be indulged whilst we set forth some general principles.

The skin must be scratched or scraped until the blood appears. If the blood flow freely, the virus

[1] Proceedings of the Académie de Médecine—Journal de Thérapeutique, No. 2, 1832.

should not be inserted until the flow has ceased; otherwise the virus may be washed out. Points of ivory, quills, or capillary tubes may be used. The lymph should be taken from the vesicle when its contents are becoming turbid. As soon as possible the points or quills should be used. The writer has vaccinated successfully with lymph contained in capillary tubes that had been put up in Germany and transported to the heart of this continent. The German method, which consists in mixing the lymph with glycerin, and storing in capillary tubes, is a good one. Crusts are much employed in this country. They possess the advantage of facility in handling and in transportation, but they are not so active and certain as the lymph taken at the most active period. It has been conclusively demonstrated that three or four points of insertion and resulting pustules are much more protective than one. The practice in Germany and on the continent of Europe generally, of inserting the virus at three points, is supported by an abundant experience. Vaccinators in this country, unfortunately, as a rule, puncture at one point only.

Whenever it is practicable, "arm to arm vaccination" should be employed. The vesicle at its most active period should be opened, and the lymph immediately transferred to the child at hand prepared to receive it. In this way the deterioration by storage and preservation is avoided.

As children are peculiarly liable to small-pox, vaccination should be performed at the earliest period—from one month to six weeks after birth in the case of a robust child, and at two or three months if the child is feeble. If exposure occur at birth, the child may be vaccinated as soon as born. It is a sound rule to vaccinate without delay all who are subjected to any special exposure. If delay may be allowed, a child should not be vaccinated if suffering from any acute disease, or from any chronic disease that interferes with the orderly development of the vaccine disease. Acute febrile affections, diarrhœa, and certain cutaneous maladies, as herpes, eczema, and intertrigo, especially, but including all affections of the skin.

Phenomena of Vaccination.—At the end of the second or third day after humanized lymph has been inserted successfully, a little papule has formed, which by the fifth or sixth day has developed into a vesicle, with an elevated border and a central depression, and having a bluish-white tint. By the eighth day after the insertion of the lymph, the vesicle is found to be full of a clear lymph just becoming a little cloudy; it is round, full, its margin elevated and its centre umbilicated; it has a distinct pearly tint, and an areola is forming around. This areola is an inflammatory ring, having a diameter of one or two inches, and rather hard and brawny, because of the swelling of the subcutaneous connective tissue. At this time, also, there is some feverishness, a coated tongue, and there may be, also, some nausea and diarrhœa. These constitutional symptoms may be slight, sometimes entirely wanting, but if absent, and no areola has formed, a suspicion may be well entertained that the vaccination is not genuine. The areola begins to fade after the tenth day. The vesicle which had developed into a round, convex pustule, begins on the tenth day to dry in the centre, restoring the umbilication, and by the fifteenth day a scab has formed. The scab, as it dries, darkens into a mahogany color, and is detached from the twentieth to the twenty-fifth day. A perfect vaccine scab or crust is round, with an elevated and bevelled margin, a central cup or depression, and has a dark-brownish or mahogany color. The cicatrix is often permanent, lasting through life, and it has certain characteristics by which the genuineness of the vaccination may be determined. It is circular, depressed below the general level of the integument, and distinctly foveated or pitted. When, in consequence of the manner in which the lymph is inserted, several vesicles form in such proximity as to coalesce, the scar will have corresponding characteristics.

Before vaccinating, if delay is allowable, an inspection of the ears and of the skin generally for patches of eczema, intertrigo, etc., should be made. In scrofulous children, so simple an irritation as vaccination, will excite cutaneous troubles, and the locality of the cicatrix may be the seat of strumous ulceration, causing protracted suppuration, enlarged lymphatics, etc. Erysipelas has been developed in some constitutions about the punctures, and spread widely, accompanied by severe constitutional symptoms. Eczema, if it be present in some obscure situation, may begin at the site of vaccination and extend over the body. Very violent phlegmonous inflammation, followed by swelling, and even suppuration of the axillary glands, may be caused by vaccination in some subjects. Much more often is revaccination followed by the accidents above mentioned.

As certain rashes occur during the invasion or prodromal period of variola, so eruptions appear during the course of the vaccine disease. In an address delivered before the Dermatological Section of the International Medical Congress, in London August 5, 1881, Dr. Gustav Behrend[1] gives a good account of the "vaccinal eruptions." He divides them into two groups: vaccinal local diseases; general eruptions. To the former belong the erysipelatous inflammations and eczemata of various kinds. As regards the general eruptions Behrend finds them to be rather rare. "In my position, as public vaccinator," he says, "among the three hundred cases which I vaccinated during the past year, I have observed them only six times." Roseola vaccinia is the only one which has been carefully described. It appears about the third to the eighteenth day, resembles measles strongly, is evenly distributed over the body and appears sparingly on the extremities, and lasts about two days. A second group of vaccinal exanthemata, consists of urticarial eruptions; and a third group of erythematous exudative processes. Also, a vesicular eruption, herpetic and eczematous, appear at various times. In the discussion following Behrend's paper, Prof. Hardy, of Paris, maintained that there are three kinds of vaccine eruptions: exanthemic, diathetic, and generalized vaccinia.[2] But Behrend holds that

[1] Archives of Dermatology, Oct., 1881, p. 383. Also, Edinburgh Med. Journal, Dec., 1881—a paper by Dr. George Thin, on same.
[2] Edinburgh Medical Journal, supra.

"a general vesicular eruption is, however, not a general eruption of vaccine lesions, not even when the vesicles resemble the latter in external appearance, and are developed simultaneously," and that they can be regarded as vaccine vesicles "only when it can be proved that their contents are inoculable, and capable of producing normal vaccine vesicles."

The appearance of vaccinal eruptions proves only that a foreign material is circulating in the blood of the affected individuals—the vaccine lymph. The eruptions of the second period must rather be attributed to the absorption of the contents of the pustules. (Behrend.)

Revaccination.—If carefully selected lymph, whether bovine or humanized, only were used; if every case of vaccination were carefully observed throughout, and repeated at the proper time if imperfect; if three or four distinct and sufficiently separated punctures had been made, it is probable that there would be less necessity for repeating the operation from time to time; it is probable, indeed, that the protective influence would continue during life in many cases. Revaccination may be necessary to supplement the original when imperfect, and to remove the susceptibility to the variolous poison which may have been reacquired. It is by a repetition of the vaccination only that the existence or absence of a susceptibility to small-pox can be determined. It follows that revaccination should be practised whenever the individual is exposed to the disease. In the absence of a special liability to contagion, there are certain periods when revaccination should be practised. These periods are: 1. After the second dentition; 2. After the period of puberty. To these should be added after the first dentition if but a single cicatrix remain, especially if not well foveated, and if faint. The influence of revaccination over the occurrence of small-pox is well exhibited in the statistics of armies. In the Bavarian army, compulsory revaccination since 1843 has been enforced. From that time to 1855 there had not been a single case of small-pox, and not a single death from the unmodified disease or varioloid. The returns of the French army are very striking. Before the year 1859, according to M. Levy (*Rapport sur les Progrès de L'Hygiène Militaire*, 1867), the ratio of deaths from variola and varioloid, per 1000 deaths from all causes, was thirty-nine. After new instructions from the Minister of War, requiring general revaccination, the proportion of deaths fell to 17.5 per 1000 deaths from all causes. This ratio was still further reduced so that, in the three years from 1863 to 1865 inclusive, it fell to 13.5 per 1000 deaths from all causes. In the Prussian army, since revaccination is enforced on all, epidemics of small-pox have ceased to occur. (Curschmann.)

Dr. Carpenter, the distinguished physiologist, has published some striking observations on the influence of vaccination amongst the civil population of England. "He shows that in the olden time, say from 1616 to 1780, the average mortality from small-pox was 4,483 per million; that with the discovery of vaccination, it fell to 2,040; with the provision of public vaccination, to 400, and under the compulsory vaccination system it had fallen to 276."[1] He showed further that the loss by death was but a part of the evil. Of those who escaped death, a considerable number were shockingly mutilated; he himself had seen 100 cases of blindness. In commenting on these statements, the *Lancet* further remarks, that "about 90 per cent. of persons in an unvaccinated community exposed to small-pox will catch it; from a third to a half would die, and the rest would be marked for life." And yet this is the state of society to which the bigoted opponents of vaccination would return.

The present epidemic of small-pox in this country means the neglect of vaccination, or its imperfect performance. A compulsory law, the provisions of which cannot be evaded, must be enforced in all the States, if epidemics are to be avoided. Unfortunately many foreigners, Germans especially, signalize their appreciation of their liberties by violent opposition to a measure enforced in their old homes by a vigorous and inflexible law. Others are content to be vaccinated by barbers, and no attention is paid to the source and characteristics of the virus. Revaccination is neglected. Until these abuses are reformed, epidemics of small-pox will recur from time to time, as new and unprotected material is produced.

[NOTE.—The writer of the foregoing has simply attempted to compile such facts as may be of interest at this time, when small-pox is so prevalent. He has not aimed at completeness, for a full account of the variolous diseases would take up a considerable volume. He wished more especially to lay before the readers of THE MEDICAL NEWS such points as may facilitate diagnosis, and clear up doubtful questions.—R. B.]

THE SURGICAL ASPECTS OF SMALL-POX.

BY J. WILLIAM WHITE, M.D.,
DEMONSTRATOR OF SURGERY AND LECTURER ON OPERATIVE SURGERY IN THE UNIVERSITY OF PENNSYLVANIA, SURGEON TO THE PHILADELPHIA HOSPITAL, LECTURER ON VENEREAL DISEASES IN THE UNIVERSITY, ETC.

THE complications of variola which are of especial surgical interest occur during the eruptive stage, or appear as sequelæ during or after the stage of desiccation. They are almost without exception attributable to the presence and local irritation of the pustules, to a depraved condition of the blood, or to actual septicæmia, or pyæmia.

A full consideration of the various conditions included under these heads would extend far beyond the prescribed limit of this article; but it may possibly be of advantage, in view of the prevalence of the disease, briefly to mention those which have been found, by reason either of their gravity or their frequency, to be of the greatest importance.

The pharyngitis and laryngitis, which to some extent are almost constant accompaniments of the early stages, assume in exceptional cases an acutely œdematous, a suppurative, or a diphtheritic form, which rapidly proves fatal. Trousseau records three cases, in which, at about the middle of the second week, death occurred from suffocation, and so sud-

[1] The Lancet, February 11, 1882.

denly that no assistance could be rendered. In one a pustular inflammation below the glottis was discovered; in another there was œdema of the aryepiglottic folds, and a large abscess was found between the œsophagus and the larynx. In a child of twenty months, dyspnœa having necessitated tracheotomy, two false membranes were thrown out through the wound at the moment of opening the windpipe; and the autopsy revealed that the pseudo-membranous inflammation had extended to the larger bronchial tube. Rühle believes the essential peculiarity of the laryngeal affection to be a croupous or diphtheritic inflammation; and Mackenzie states that examples of this complication are to be found in the museums of St. Thomas's and St. Bartholomew's Hospitals. The histology of this complication is thus described by Cornil and Rauvier: "In confluent variola, the larynx, and, indeed, the mucous membranes of all the air-passages, are the seat of pustules more or less numerous. The pustules of the larynx have, generally speaking, the same form and evolution as those of the skin. When the pustules are very numerous, they unite into groups, and the epithelial layer, degenerating over an extended surface, forms a veritable false membrane, which, in certain cases, might be confounded with the false membrane of croup. After the shedding of the epithelium, the pustule continues to empty itself; the superficial layers of the mucous membranes may continue to suppurate; there is then formed an ulcer more or less deep and irregular." More severe inflammations, abscesses, and perichondritis have been observed towards the end of this process.

The treatment should consist, in the slighter cases, of astringent gargles, followed by scarification of the larynx, if œdema occur; in the more serious cases, where alarming suffocative attacks are met with, tracheotomy, at an early stage, offers the best, if not the only, chance for recovery.

The ophthalmia of small-pox, which is more destructive than that accompanying any of the other exanthemata, is usually confined to the lids and lachrymal apparatus during the eruptive stage, but may involve the cornea itself, or, more rarely, the other structures of the eye. The opinion that characteristic pustules form in these localities, though strongly opposed by some authors, still seems to be the prevalent one. A "secondary variolous ophthalmia" is described, occurring after complete desquamation, or even as late as the fifth or sixth week, and consisting of corneal abscess, followed by leucoma, or staphyloma.

Destructive inflammation of the bones of the nose has resulted from an extension of inflammation from the Schneiderian membrane, and profuse epistaxis, due to ulceration, has in a few instances either directly terminated the case, or has reduced the patient below the rallying point.

Particular attention should be paid to the condition of the tympanum, the middle ear, and the mastoid cells, as purulent otitis, followed by caries, has occurred. This complication, in young children, has been thought to cause death, and is undoubtedly capable of giving rise to coma, to convulsions, and to other grave symptoms.

Phlegmonous erysipelas of the scalp has proved fatal in a few cases, and, indeed, the association of profoundly vitiated blood with the intense irritation of the pustular dermatitis would seem to offer such favorable conditions for its development that its infrequency appears somewhat remarkable. It was, however, found to affect some portion of the body in forty-seven out of two hundred and eighty-seven cases recorded by Sargent in the *American Journal of Medical Sciences*, April, 1849.

A series of localized inflammations of subcutaneous cellular tissue, in the shape of furuncles, may follow the eruption; and in some reported cases there have been as many as eighty or a hundred boils upon the surface of the body at one time. Oftener they exist in smaller numbers, but follow each other in successive crops, extending over a period of months. This condition has been called a "furuncular diathesis," and is probably an evidence of a depraved state of the blood, which prevents healthy reparative action in regions more or less implicated in the profound dermatitis of the eruptive stage. A more dangerous form of extension of inflammation results in the production, during convalescence, of deep-seated abscesses, usually in the limbs. The progress towards health is interrupted by the usual symptoms of suppuration, rigors, fever, pains, etc.; and soon afterwards fluctuation develops often in the deeper muscular layers of the extremity involved. These collections of pus may occupy the ischio-rectal fossæ, and result in perineo-rectal fistulæ, or in extensive sloughing of the buttocks.

Œdema of the legs and feet is said to be rarer than in scarlatina, and more frequent than in measles.

At about the period of subsidence of the salivation, the dysphagia and the laryngitis, which occur soon after the appearance of the eruption, or, in other words, at a period corresponding to the height of the suppurative or secondary fever, we often have well-marked genito-urinary symptoms; intense ardor urinæ, vesical tenesmus, hæmaturia, orchitis, and acute hydrocele in the male, or ovaritis in the female. These complications have all been attributed to the occurrence of the eruption in the parts affected; but it seems probable, as the mucous membranes are, after the skin, the tissues pre-eminently involved in this disease, that the orchitis may often be, as usual, secondary to a urethritis.

That small-pox in its eruptive stage may, however, affect the serous membranes, as well as the skin and mucous tissues, was pointed out a century ago by Pedzholdt, who published his observations on variolous meningitis and peritonitis in 1832–1833. More recently—1859—M. Béraud called attention to these forms of orchitis and ovaritis, which affect not only the parenchyma of these organs, but involve the tunica vaginalis, producing the acute hydrocele above mentioned; or, by attacking the folds of peritoneum covering the ovaries, give rise to a circumscribed peritonitis.

Gangrene of the scrotum, or of the labia, has occasionally been seen, the loose, subcutaneous connective tissue of these parts, and their dependent position, favoring the rapid extension of the inflammation from the derm, and the arrest of the blood

current. Gangrene of parts exposed to pressure has also been noted very early in cases in which the blood was extensively altered.

Lymphangitis and buboes frequently occur during the acute stage, the inflammation of the glands often going on to suppuration, which, as in most similar cases, affects by preference the peri-glandular cellular tissue, but occasionally invades the structure of the gland itself.

Arthritis is a surgical accident of the secondary stage, which is far from uncommon. It belongs to the same class of joint affections as those occasionally complicating urethritis, lacerated wounds, puerperal fever, albuminuria, and scarlatina; but, like all the variolous inflammations, has an almost uncontrollable tendency to suppurative action, and, indeed, usually begins as a purulent synovitis. Extra-articular suppuration has occasionally followed, either by the extension of inflammation through the synovial membranes to the subcutaneous and capsular structures, or, as a result of purulent extravasation, from rupture of the synovial sac.

In such cases the patient will be left with sinuses discharging an ichorous fluid, with much limitation of the movements of the joint, and with a tendency to hectic, which may terminate the case fatally.

Periostitis, which is an occasional complication, shows the same tendency to suppuration, and is often followed by caries and necrosis either from the formation of a subperiosteal abscess, or as a result of a secondary osteitis. The latter condition is in exceptional cases the primary one.

Small-pox, like the other eruptive fevers, often so affects and interferes with the developmental processes of young children as to leave its impress upon the osseous tissues, predisposing to subsequent deformities or producing tardy or irregular growth.

In the dental structures this is easily noticed, teeth erupted during or soon after convalescence being marked with a series of parallel horizontal grooves, showing the failure of the nutritive supply during the period of the fever. These marks, of course, persist throughout life. It must not be forgotten, however, that, even if the variola occur some time before the eruption of the first permanent teeth—the sixth-year molars—that it may affect them and all those which follow. While the development of the temporary teeth is advancing, the germs of the second set are also progressing, and the occurrence of a stomatitis, such as small-pox invariably gives rise to, would of itself, exclusive of the general or systemic disturbance, be sufficient to interfere with the nutrition of the teeth, the blood-supply to which is at once vitiated and greatly diminished.

The necrosis of the maxillary bones, which sometimes occurs in children after the exanthemata, has been attributed by Mr. Salter to the influence of the fever poison upon the delicate tooth pulps, which, as dermal organs—portions of the tegumentary system—are especially affected by the diseases which chiefly attack this system.

Finally, septicæmia and pyæmia, followed by metastatic abscesses, occur during the *stadium maturationis*, and carry off a not inconsiderable proportion of patients. Ribes and Legallois have endeavored to show that the starting-point of the purulent infection in these cases is a capillary phlebitis, and, although this has not been conclusively demonstrated to exist in every instance, it seems exceedingly probable that it gives rise not only to many pyæmic manifestations, but also, through the production of embolism, to the sudden deaths which now and then occur during the height of the disease.

In the treatment of all these affections no deviation from ordinary surgical practice is required—abscesses should be opened when mature, local inflammations should be controlled in the usual manner, and gangrenous parts should be interfered with only after nature has entirely effected their separation. Treatment of special symptoms should, of course, be subservient to the general management of the case. A cardinal rule, however, is to avoid, under all circumstances, anything approaching systemic depletion, and to interfere surgically only when it becomes apparent that such intervention is necessary to save important structures, or life itself.

HOSPITAL NOTES.

THE PHILADELPHIA DENTAL COLLEGE.

HOSPITAL OF ORAL SURGERY.

RADICAL TREATMENT OF EPITHELIOMA.

(Service of JAS. E. GARRETSON, M.D.)

IN the treatment of epithelial cancer, Prof. Garretson urged as his experience that thorough removal of an affected part and its replacement by a flap brought from the greatest possible distance, had seemed to inaugurate a physiological change and arrest of development of the abnormal cells. Whether this was due, he said, to something approximating a condition which might be termed *force of example*, he would not at this time digress to consider, but would content himself with reference to the fact that for thirteen years he had practised the operation with satisfactory success on quite a large number of cases.[1]

The disease in the patient upon whom he was about to operate involved both eyelids of the right side, extending down upon the cheek, the contents of the orbit, the internal and inferior bony floor, both nasal bones, the perpendicular lamella, and cribriform plate of the ethmoid bone, and the internal angular process of the frontal bone. The gravity of the condition was self-evident. That epithelioma so related could scarcely fail to quickly prove fatal, could not but be admitted by all who were present.

The patient was, however, as yet rugged, with the bloom of health, and without signs of cachexia. The danger attending such an operation as was required, was fully understood by the man, who was most desirous that the attempt be made to save him. Humanity's and the patient's sake both impelled the lecturer to undertake the operation, which he proposed should be the plastic one referred to, as it offered the only possible chance of life to the individual, while at the same time it was an extreme example to distinguish the promise and capability of the means of cure.

After etherization was completed a section was made over the frontal prominence and carried down the nose to the ala upon the right side; thence across that cheek

[1] See his System of Oral Surgery, also the last edition of Dr. Duhring's Treatise on Diseases of the Skin.

to the angle of the jaw, from whence back to the place of departure. The soft parts included in these boundaries were then dissected out, including the right eye and its appendages, and the bony parts previously mentioned were removed, as they proved upon examination to be involved in the disease. For this purpose the surgical engine armed with an oval burr was used, proving a most efficient and valuable machine, capable of the most delicate and trustworthy work. It was claimed that the burr was revolving at the rate of fifteen thousand times per minute, and yet the operator was exposing the olfactory bulbs of the brain.

The abnormal tissue being entirely removed and the severed arteries secured, the integuments across the temporo-zygomatic region were separated and dissected up slightly to beneath the ear, in order to form a wide groove along which the flap could be laid. A great flap with a pedicle of one and a half inch in width was now taken from the integuments beneath the right ear extending down to the scapula, being about seven inches in length, having an enlarged termination of some four inches across. This flap was then turned and stitched into the margins of the skin about the ablated parts.

Three days later a crucial incision was made into the part overlying the orbit and the four ears thus secured were worked around the circumference of the cavity and retained in their new position by a conical-shaped sponge compress supported by a monocular bandage.

Three days after the operation the patient was sitting up in his bed reading with his single eye.

MEDICAL PROGRESS.

ALCOHOLIC INTOXICATION.—In the blood of animals in a state of alcoholic intoxication a notable quantity of alcohol was found by Lallemand, Perrin, and Duroy. The method which they employed was to draw from the carotid artery a considerable quantity of blood, to distil this in a salt bath, and to redistil over quicklime. M. GRÉHANT has endeavored, by a modification of this process, to ascertain what proportion of alcohol in the blood is sufficient to produce and to maintain symptoms of intoxication. The value of the method and apparatus employed was first tested by examining with it definite mixtures of blood and alcohol, and it was ascertained that if pure blood was thus treated no trace of alcohol could be discovered in the distillate. Two hundred and thirty-one grammes of alcohol (21° stength) were administered to a dog in two doses, at an interval of half an hour. At the same time the animal was made to breathe through a flask containing absolute alcohol, in order to counteract the influence of pulmonary exhalation. At the end of an hour, one hundred litres of air having passed through the flask, sixty-eight cubic centimetres of blood were drawn from the femoral artery. They were found to contain .345 cubic centimetres of absolute alcohol, which corresponds to one part of alcohol in one hundred and ninety-seven of blood. This proportion, in the case of the animal experimented on, was sufficient to produce the most profound intoxication.—*Lancet*, Dec. 10, 1881.

HUNGARIAN EXPERIMENTS ON ANTHRAX.—At the last meeting of the Hungarian Natural Science Society, Dr. Rozsahegyi gave an account of some experiments on the prophylactic inoculation of anthrax, initiated by M. Pasteur. An attempt was made to communicate the disease to a series of inoculated sheep, and to others which had not been inoculated, and it was found that the death-rate in the latter was 93 per cent., in the former only 1.45 per cent. If, however, regard was paid not only to the deaths which resulted from the infection of anthrax, but also to the total mortality from all causes during the experiments, this difference, was found to be somewhat less, the mortality among the inoculated animals being 14 per cent., and among the others 94 per cent. The large mortality in the protected animals from other causes than the subsequent infection seems to show that the process of inoculation is not itself free from considerable risk, either directly, or indirectly by rendering other diseases more fatal. Another point of importance raised, but not answered, is the question, Within what time may the flesh and milk of inoculated animals be regarded as free from all danger of conveying the disease to man? —*Lancet*, Jan. 14, 1882.

THE INTRA-UTERINE APPLICATION OF PERCHLORIDE OF IRON.—Dr. VON TEUDLEBEN (*Centbl. f. Gynäkol.*, No. 24) recommends, as obviating any danger that may arise from the use of injections into the uterus, the use of solid perchloride of iron made into sticks and kept in sealed glass tubes. These are to be introduced into the uterus inclosed in a perforated cannula, which must be moved freely about in the cavity. A few minutes suffice for the complete solution of the stick. He refers to Martin's perchloride pencils, which are compounded of the salt with glycerin and powdered althæa root, and are, therefore, in his opinion, not so useful as the ones described.—*Edinburgh Med. Journ.*, Jan., 1882.

RECURRING LETHARGY.—A remarkable case of lethargy is now to be seen at the Hospice-Général at Rouen. For twenty days a woman, thirty-seven years old, has been in a profound sleep, which is broken for a few moments each night, when she takes some food. The sleep is accompanied by general rigidity, so that the whole frame can be raised as one piece. Her first attack was fourteen years ago, and periods of lethargy have recurred since from time to time. During the intervals she seems perfectly well, and has been employed at the hospital as nurse. Just before the onset of an attack she becomes nervous and taciturn. The onset is always sudden; she goes to sleep in a moment, whatever she may be doing. During the lethargic state the face is well colored and warm, and respiration is regular, but there is, as stated, general muscular rigidity. About half-past ten each night the legs begin to tremble, slight groans are uttered, and are precursors of the brief nocturnal remission. At eleven o'clock she opens her eyes, sits up and eats what is given to her without speaking. Then she again puts her head on the pillow and goes to sleep, but the limbs are relaxed until about four o'clock in the morning, when the rigidity again comes on, and lasts until the following night. Twice she has slept continuously for ninety-six hours without taking food. She does not lose flesh. The long period during which these attacks have recurred, and the form of fixed, not cataleptic, rigidity, render the case unusual, even among the rare instances of lethargic trance.—*Lancet*, Jan. 7, 1882.

RHEUMATIC ŒDEMA.—Prof. POTAIN (*Journ. de Méd. Pratique*, Nov., 1881), draws attention to a form of œdema supervening under the influence of the rheumatismal diathesis, which is usually of favorable prognosis, but which at first sight might seem to be due to some serious affection, as disease of the heart or kidneys. This œdema is recognizable by its mobility, the good general condition, and the absence of any cause beyond antecedent or co-existing arthritic manifestations. It is marked by a peculiar consistency or hardness, as if the liquid remained confined within the cells. Sometimes these tumefactions become more localized, and then may be mistaken for tumors or collections of fluid. Rheumatic œdema indeed shows itself under

extremely variable appearances which may easily give rise to errors of diagnosis.—*Med. Times and Gaz.*, Feb. 11, 1882.

IODINE IN MALARIA.—In the *Maryland Medical Journal* for February 15, 1882, Dr. R. B. MORISON reports two hundred and fifty cases of malaria treated with tincture of iodine in fifteen minim doses, largely diluted, a quarter hour before meals. His cases show an even more favorable result than where cinchonidia is employed, and he states that iodine is now the routine treatment in all cases of acute malaria coming to the dispensary. Similar observations are reported in the *Indian Medical Gazette*, for January, by BABOO BROJENDRY NATH BAMERJEE at the meeting of the Calcutta Medical Society. He states that since 1878 he has made large use of this method of treatment, and in 1879 published in the Calcutta *Medical News* that he had cured ninety per cent. of five hundred cases. Since then, however, he has been led to distrust the reliability of his results, and believes that many of his earlier trials were made in cases which recover spontaneously, while others of these cases last, even under no treatment, only one day. Under such circumstances any drug will appear to act like magic. His present belief is that iodine will prove serviceable in about half the cases. The same author also reports cases in which *burnt alum* appeared to be of service.

ADDISON'S DISEASE.—An interesting contribution to the pathology of Addison's disease was brought by Dr. GOODHART before the last meeting of the Pathological Society, and gave rise to a still more interesting discussion. The cases briefly consisted in atrophy or complete disappearance of the supra-renal capsules, associated with all the clinical features of Addison's disease in a marked degree. It would appear, therefore, that the changes in the capsules which Addison and all subsequent writers have considered essential to the disease may, after all, be only one of several conditions capable of giving rise to this group of symptoms. Many facts were brought forward in support of this opinion. Dr. Goodhart himself was of opinion that such cases as these strongly suggested the view that changes in the abdominal sympathetic were the real source of the symptoms—a view which was traversed by Dr. Pye-Smith, who, after pointing out that the adrenals were obsolete organs in adult life, the removal or destruction of which in animals produced no effect, warned his hearers against the acceptance of this neurotic theory, on the ground of its extremely simple and seductive nature. He supplemented this by pointing out that pigmentation of the skin was very common, and that there was neither pathological nor physiological analogy in support of melasma being due to nerve-changes. Dr. Coupland was hardly prepared to accept Dr. Pye-Smith's views, and pointed out the striking analogy presented by the vomiting and pigmentation of pregnancy in support of disorder or implication of the abdominal sympathetic. He did not think that structural changes need necessarily be found in the nerve-ganglia themselves, although he had met with one notable example, where fibrosis with atrophy of cells existed. He expressed his belief that the changes in the supra-renal capsules were of the nature of a localized tuberculosis, which might take place without any symptoms of Addison's disease. Dr. C. Creighton, in regard to the function of these bodies, referred to the researches which had shown that the blood issuing from the capsules gave chemical reactions different from those which were obtained from blood entering them, and argued that changes, such as atrophy or caseation, which practically cut off the blood-supply, might lead to such alteration in the blood as would bring on pigmentation, while cancerous changes, which increased the circulation through the organs, would have no such effect. Finally, Dr. Fowler referred to a case of lymphadenoma in which the abdominal sympathetic was largely invaded, where the capsules were healthy, and in which all the symptoms of Addison's disease were present.—*Med. Times and Gaz.*, Feb. 11, 1882.

CICATRICIAL OBLITERATION OF THE PYLORUS.—M. DUJARDIN BEAUMETZ communicated to the Société Médicale des Hôpitaux, on January 13, a curious instance of cicatricial obliteration of the pylorus in a midwife who had swallowed sulphuric acid six years previously. Since then the stomach had become enormously dilated, and it had been proposed to perform Billroth's operation of suturing a loop of intestine to the wall of the stomach, after having formed a communication between the two organs. Unfortunately the woman died before the operation was undertaken.—*Gaz. Méd. de Paris*, Feb. 4, 1882.

TESTS AS TO THE PURITY OF CHLOROFORM.—In the *Progrès Médicale*, Dec. 31, DR. YVON refers to certain tests of the purity of chloroform published some time since by Prof. Regnauld, which the surgeon may resort to himself. These are: 1. The sweet odor of the chloroform. 2. It should not redden litmus-paper. 3. It should give no precipitate, nor even produce turbidity, when shaken with a solution of nitrate of silver. 4. It should not become colored when carried to a boiling-point with concentrated solution of caustic potash. 5. Sulphuric acid should not be blackened when brought in contact with chloroform. Other tests can only be practised by the chemist, such as the determination of the density and boiling-point; but Prof. Regnauld states that no chloroform can be regarded as pure which does not satisfy the above-named conditions. But, however pure chloroform may be, it is continually in danger of undergoing spontaneous changes, so that its purity requires verification from time to time; and when it is kept in a bottle incompletely filled, more or less imperfectly corked and exposed to the light, this is soon diminished. For the detection of the changed condition, even before it becomes dangerous, M. Yvon employs, as a test, permanganate of potash one part, caustic potash ten parts, and distilled water 300 parts by weight, which form a solution of a beautiful violet red. This, brought into contact with chloroform that has been rectified, does not change color; but if the rectification has been incomplete, it is more or less rapidly reduced, its reduction being preceded by a change of color to green. This permanganate in solution, therefore, supplies the *pharmacien* with a most delicate and rapid test of the purity of the chloroform furnished to him, and, employed from time to time, ascertains whether the original purity is still maintained.—*Med. Times and Gaz.*, Feb. 11, 1882.

PITYRIASIS.—Prof. HARDY recommends the following mixture in the treatment of pityriasis: Bicarbonate of soda, 20 grammes; arseniate of soda, 10 centigrammes; distilled water, 300 grammes. A spoonful to be taken before breakfast and dinner in the pityrisis rubra of gouty subjects, in disseminated pityriasis, and in pityriasis of the beard or hairy scalp—when the bicarbonate of soda given alone has proved inefficacious. For lymphatic subjects affected with obstinate pityriasis rubra of the armpits, groins, or neck, the arseniate of iron may be prescribed with good effect in doses of two or three centigrammes per diem. As a local application we may use ointments of oxide of zinc, and, later on, those of tar, of juniper, oil of cade (from a tenth to a twentieth), of calomel (from fifty to a hundred parts), or citron ointment mixed with ten parts of cold cream or lard.—*L'Union Méd.*, Jan. 21, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, MARCH 4, 1882.

THE SMALL-POX EPIDEMIC.

DURING the existence of the present small-pox epidemic we have kept our readers duly informed of its progress. So important is the subject, that we begin in the present issue a tolerably full account of the disease. We are sure that our efforts to illuminate the subject of the variolous diseases will be regarded as timely by our readers, who desire full information on current medical questions. We had intended to devote one issue wholly to variola—a small-pox number—but the pressure on our columns is such, that we can give a part of two numbers only to this topic.

NEPHROTOMY.

IN an editorial in our issue of January 21, we called attention to the general matter of abdominal surgery. The surgery of the kidney is worthy, however, of more especial notice.

Two new terms have been recently added to our surgical nomenclature, which, though not yet always recognized by our surgical writers, are not only convenient, but exact, viz., Nephrotomy, to indicate a cutting operation on the kidney; and Nephrectomy, to indicate its total extirpation. While the latter is exclusively a modern operation, the former was recommended by Hippocrates, and was done in the seventeenth century by Marchetti on Mr. Hobson, the British Vice-Consul at Venice, and probably by the Paris faculty on an archer of Bagnolet. But it fell into entire oblivion until 1869, when, in a thoughtful paper, Mr. T. Smith recalled attention to it, and Mr. Annandale also declared in favor of operative interference. Mr. Bryant, in the recent edition of his *Surgery*, though he has done the operation four times, cautiously says, that "it is probable that in a few years it will be recognized as an operation." But so long ago as 1878, Torres had collected one hundred and sixty-three cases of various operations on the kidney, and properly says, "at present a new period of action in renal surgery is opening. Nephrotomy and nephrectomy are among the orders of the day."

Nephrotomy may be called for by either renal calculus or renal abscess. Even if no stone be found, yet, in the apparent failures of Durham and Annandale, the patients have been so vastly relieved of their nephritic colic as to justify the operation in these cases, and to suggest its advisability in others.

The diagnosis of abscess, and, still more, of calculus, of the kidney is by no means always easy; yet, with our present means, it is rendered sufficiently certain in many—if not in most—cases to make an exploratory operation, at least, entirely justifiable and even imperative. Usually only one kidney will be affected. This may be so even as a result of stricture, as in the remarkable case of Mr. Puzey. The same case, as well as those of Mr. Dowse and of Prof. Simon, shows a sort of see-saw relation between the condition of the urine and the nephritic attacks. During the attacks the urine was normal; but so soon as the pressure of the accumulating pus was sufficient to force it into the bladder, the attack was relieved. Given, says Mr. Puzey, the state of the patient, and the character of the urine could be predicted; or, given the state of the urine, and the condition of the patient could be inferred. Such normal urine occurring during an attack is most important evidence of the soundness of the other kidney. Of course, in an abscess, the use of the aspirator would occur to any one; but Mr. Barker has pointed out an additional value it has in renal diagnosis. He used it in a case in which it was doubtful whether the disease was a new growth, tubercular infiltration, or a calculus. When the point had penetrated the skin the vacuum was produced in the needle, and he hoped that, in case of either of the first two conditions, to get enough tissue *débris* to enable him to diagnosticate its character microscopically, or, if a stone were present, he would obtain the evidence of its presence not only by the pus, but by the grating of the needle against it—a result in which, happily, he was not disappointed. If the introduction of the hand into the rectum be ever advisable, in such serious cases as these it would seem to be allowable, and might give most important information.

The dangers and difficulty of the operation are not great. It is practically a lumbar colotomy terminated in a slightly different manner. On reach-

ing the kidney no stone may be felt, and yet there may be, as in Simon's case, as many as eighteen or twenty. Puncture of the kidney by a needle is not only justifiable, but, as in Dawson's, Puzey's, and several other cases, the renal substance may even be cut to a considerable extent. Hæmorrhage, however, is much to be feared if this be done, unless the kidney be reduced to a sac. The use of Pacquelin's cautery knife may obviate to a large extent this danger.

Not uncommonly the stone, instead of being a simple, uniform body, like a urinary calculus, will be irregular, with branches extending into the calices of the kidney, and will be so imbedded in the pelvis as to require crushing and piecemeal removal —of which Le Dentu gives an excellent example. The existence of internal renal fistulæ, so far from being a contra-indication, is, as Simon has pointed out, a still stronger reason for doing it, in order to avoid their fatal results. Puzey, some time after the operation, was able even to catheterize the ureter down to the bladder.

The results of the operation are most encouraging. We lack yet the exact data as to the recoveries, but they are no doubt very largely in excess of the deaths, and the greater number not only recover from the operation, but are restored to perfect health without even lumbar fistulæ. The other kidney, as Torres has shown experimentally, undergoes compensatory hypertrophy, and the urinary function goes on undisturbed. If nothing be done, spontaneous recovery, according to Torres, follows in but one case in fourteen, or only about 7 per cent., a mortality far greater than that following nephrotomy.

THE PROPAGATION OF THE "FOOT AND MOUTH DISEASE."

The recently published report of Dr. Charles P. Lyman, the veterinary surgeon sent to England by the Commissioner of Agriculture to investigate the "foot and mouth disease" in exported American cattle, impresses us much by the author's carefulness and success. That it was a serious matter will appear when it is considered that about twenty-eight hundred American cattle were condemned and slaughtered from January to June last.

Dr. Lyman first traced the cattle from their very stables in the West to the vessels; found them free from disease on embarcation; and found that the disease broke out usually in the ocean transit between this country and England. Then he investigated the vessels and cargoes, thinking that they might be the sources of contagion, especially as hides, skins, and wool, were often among the freight, but he could discover no connection between them.

But still more careful investigation showed that the "head-ropes" fastened to the horns of the animals to secure them in their stalls were frequently sent back from the lairs in England to be used again with the next lot of cattle, and that these clearly carried the infection. For instance, the "Iowa" left Liverpool April 12, with four bundles of such "head-ropes" among her cargo. She left Boston April 30 with eight hundred and forty-nine cattle all healthy, until May 7, four days before she reached Liverpool, when the "foot and mouth disease" broke out, and on her arrival on the 11th six hundred and forty-nine of the cattle were condemned. She had never carried any live stock from England to America. Dr. Lyman recommends the clear and simple remedy of prohibition by law of all such re-importation of "head-ropes."

Such methodical work, whether in diseases of man or animals, will not only do great good but reflects credit upon the man that does it.

CONSULTATIONS WITH IRREGULAR PRACTITIONERS.

The new Code of Ethics adopted by the New York State Medical Society, has called forth the unqualified approval of the secular press. Our lay contemporaries have never understood the position of the medical profession on their relations to irregular practice in all its varied forms. It is always assumed that there is a quarrel over a dogma—that it is allopathy *vs.* homœopathy—that the latter is a new form of medical belief, a protest against the ancient medical delusions. They hold that the medical profession (the "allopaths") are actuated by jealousy and bigotry, and cannot be persuaded that there is a principle involved. They do not comprehend the fact that medicine is not a dogma, and that it has the same position as the other experimental sciences. If a physician, therefore, adopts the dogma of *similia similibus*, he ceases to be in relation to medical science. If he assumes that dogma to be true, he cannot associate with those who pursue medicine in the scientific spirit. With the dogma of *similars* are connected many visionary notions, which the physician, as a scientific man, must reject. There can be no comparison of views, no harmonizing of opinions, as between a homœopathist and a physician, for the former practises on a theory and employs a method of treatment, which the latter regards as folly or dishonesty. If a doctor announces himself an eclectic, or a homœopathic, or an allopathic, or a physio-medical, or a botanical physician, he assumes a special designation which implies the possession of some special resources, not used nor in the possession of other practitioners, which is untrue. Furthermore, this special designation is a mere pretext to obtain practice in many cases, the doctor so employing it not adhering to its methods. Sailing under false colors is a kind of dishonesty which all condemn. To recognize such

as associates, and to meet them in consultation, is to approve of their tactics, and to condone their offences.

The folly of a consultation between a regular physician, a homœopathist, and a botanical doctor, may be illustrated by an example. Suppose the case were one of violent cholera morbus, the regular physician would propose to cure promptly by the hypodermatic injection of morphia, the homœopathist would advise the third to the thirtieth dilution of veratrum, and the botanical doctor would urge No. 6. It would be simply impossible to reconcile the conflicting opinions, and the consultation would consist in the assertion of their respective principles.

The medical profession, having nothing in common with the advocates of "systems," must necessarily pursue its present course, and have no relations or consultations with them. The bigotry and intolerance of which they are so freely accused, belong to those who pursue an antiquated dogma to the exclusion of modern scientific methods. If all branches (so-called) of the medical art would unite, let the irregular practitioners abandon their trade insignia, and prepare themselves to become physicians. When they do so, and pursue medicine in the true spirit of an experimental science, differences will disappear, and then consultations will become conferences for the benefit of the sick, and not, as now, impracticable for want of a common ground of action.

It was a grievous error on the part of those gentlemen who were active in creating the new code of ethics, to suppose that homœopathists were desirous of dropping their special designation. Why should they do so? They announce themselves as homœopathists, ostentatiously, because this is the shibboleth which attracts business. All who have any opportunity of observing their methods, learn that very few indeed practise homœopathically. If they were governed by conscientious motives, they could easily relinquish homœopathy, and, after a proper training, enter the ranks of legitimate medicine; but doing so, would compel them to relinquish their one claim to popular sympathy and support. It is not surprising that they are prepared to snub the advocates of the new code, and to reject with derision the overtures for the unnatural reconciliation.

The resolution lately adopted by the Royal College of Physicians of London, on the subject of consultation with irregular practitioners, we have recently seen alluded to as if by the terms of this resolution all restrictions were removed. This is a singular and unwarranted perversion of the meaning of this resolution, and of the feelings prompting its introduction and passage. The resolution expressly condemns consultation with those who "trade on some special designation," and it was passed in compliance with the sentiment of the medical profession in England, who had been deeply stirred by two addresses advocating the removal of the present restrictions made at the Ryde meeting of the British Medical Association. It was to little purpose that Dr. Bristowe and Mr. Hutchinson expended their breath; no proposal could be more universally condemned than was theirs, to have the medical practitioners of England abandon their well-founded hostility to all forms of irregular practice.

THE SURGERY OF CYSTS OF THE PANCREAS.

THE deep position of the pancreas, the extreme rarity of its diseases, and the difficulty attendant upon their discrimination, render any information upon its lesions and their management exceptionally valuable. Bécourt and Douponchel have described cysts of this organ as large as a child's head; but it is only within the past year that this class of tumors has attracted the attention of the operative surgeon. Kulenhampff, of Bremen, records the case of a man thirty-nine years of age, in whom, at the end of two months, as the result of severe blows upon the belly, received in hoisting a heavy kettle, a tumor made its appearance in the epigastrium. An exploratory incision was made on the 14th of September, 1881, and a few ounces of fluid, which proved to be pancreatic on chemical examination, were withdrawn with an aspirator. Six days subsequently, the abdomen was again opened, the peritoneum was united to the incision, and antiseptic gauze inserted into the belly with the view of exciting adhesion between the sac and the walls of the abdomen. The object having been accomplished in four days, the cyst was laid open, a litre of fluid evacuated, a tent inserted, and antiseptic dressings applied. During the next sixteen days fluid constantly escaped in gradually diminishing quantities, the tumor disappeared, and a fistulous track remained, which, under the application of tincture of iodine and nitrate of silver, had completely closed on the 30th of October. The operator alludes to a case in the hands of Thiersch, in which a cyst of spontaneous origin, and supposed to be connected with the tail of the pancreas, was opened and three litres of chocolate-colored fluid evacuated. The patient recovered, but a fistule remained.

In addition to the foregoing cases, two examples of the removal of cysts of the pancreas, being the only ones of the kind on record, were reported by Rokitansky, of Vienna, and Bozeman, of New York, both of which were mistaken for ovarian tumors. The case of Rokitansky oc-

curred in a woman, thirty-six years of age, who had suffered with signs of ovarian dropsy for nearly three years. On the 27th of February, 1881, the usual incision was made, and the cyst was found to be extensively adherent to the omentum, stomach, descending and transverse colon, the latter of which was torn to the extent of two centimetres; but the rupture was closed with five sutures. During the separation of the adhesions fifty vessels were ligated, the sac was lacerated, and the patient nearly died on the table. The greater portion of the sac was left in situ, and the outer wound closed. On death from suppurative peritonitis on the tenth day, the cyst was found to be connected with the tail of the pancreas.

The patient of Bozeman was forty-one years of age, and the disease was observed five years before the operation, which was performed on the 19th of November, 1881. After the greater portion of the fluid had been drawn off, and the attachments to the transverse mesocolon had been severed, the enlarged and tortuous splenic vein came into view, as it rested upon the pedicle of the cyst, which was three-quarters of an inch long and broad, and attached to the tail of the pancreas. This was ligated, and the operation was concluded in the usual way. The tumor, with its contents, weighed twenty-one pounds and a half. Not a single vessel required a ligature. The patient was discharged cured on the thirty-eighth day.

IT seems that in New York State there is a law requiring employers to provide seats for their saleswomen, to use when not engaged with customers. We should be very glad to learn that such a law was passed in every State. It is cruelty itself to expect women to stand up all day, as practically has been the case in some stores we know, a furtive rest on box or counter being the only relief. Even if well and strong, it would be hard, but when ailing, or when menstruating, women especially need rest. We observe that suit has been begun in New York City against seven prominent merchants to enforce the law. Whether these particular firms are at fault we do not know, nor is it material. Attention is called to the matter publicly, the existence of the law is made known, and much good we doubt not will be done—not only to women we hope, but also to men.

The matter of a reasonable time for a mid-day lunch, too, is of no little importance to working men and women. It is a difficult thing to arrange all such matters, in view of the imperfections of employers and employés, but that it can be done the testimony of Ehrich Brothers conclusively shows. We commend their honorable course, as stated to the *Tribune* reporter, to other employers, not doubting that the result will be satisfactory to both parties.

AS THE result of the discussion upon the great question of the removal of refuse matters from the vicinity of habitations, which has been actively going on for a number of years past, the conclusion has been well established that the water-carriage system is unquestionably the best adapted to the needs of cities and large towns, provided that certain conditions with regard to the construction and management of sewers be faithfully observed. The main points to be insisted on are—that the sewers should in the first place be well-constructed, they should be made water-tight, and as small as possible, so that they may be, in a measure, self-cleansing and properly flushed at stated intervals, and they should be well ventilated. The surface water should be made to go direct into the river; for if allowed to mix with the sewage it would necessitate an increase in the capacity of the sewers far above their ordinary requirements, and this fact alone would be very disadvantageous; and, moreover, it would entail an increased difficulty and expense in the treatment of the sewage at the outfall.

How many American cities can boast of the possession of a system of sewerage which meets all or any of these plain and simple requirements, is a question which, it is feared, cannot be answered without a profound sense of shame because of grievous shortcomings.

ON January 8, a sermon was delivered at St. Barnabas Church, by the Rev. Richard Hill, M.A., on the subject of "Scientific Experiments on Organic Life—a Necessity, no Sin." Seats were reserved for the medical faculty, and, it is to be hoped, they were well filled.

If discourses upon such topics from similar points of view were more frequent, the profession would probably avail itself less of what is spoken of by a recent English writer as "the well-established medical privilege of remaining away from church."

IN another column we give a brief *résumé* of the first annual report of the Thermometric Bureau of the Winchester Observatory, at New Haven. We feel a pleasure in the fact that Yale College has taken the initiative in this country in establishing such a service. Untested instruments, as the report shows, are so utterly unreliable that no medical man should be willing to trust them. Instruments of precision are worse than useless when they lack the first requisite which their name implies—precision.

IT is an interesting fact, that in some cases of locomotor ataxia, pilocarpine has apparently much alleviated the pains, and improved the condition of patients otherwise. Dr. Jennings reports a case so benefited and Prof. Ball and M. Jules Simon have

communicated other examples to the same effect. The new remedy deserves further attention.

"What constitutes a State? Men who their duties know, and sovereign law." This was Sir William Jones's opinion, and he may have been right, but we doubt whether our esteemed contemporary, the *British Medical Journal*, can with impunity observe that "Wilmington and Delaware also rank among the towns supplied with polluted water." From observed peculiarities of the Delawareans, it seems probable that they have long been familiar with the inferior character of their drinking water, but the reflection on the size of their State will doubtless result in the withdrawal of the entire Delaware patronage from the B. M. J., which should remember that "the *smallest* worm will turn being trodden on."

REVIEWS.

Minor Surgical Gynecology. A Manual of Uterine Diagnosis and the lesser Technicalities of Gynecological Practice, for the Use of the Advanced Student and General Practitioner. By Paul F. Mundé, M. D., Professor of Gynecology in Dartmouth Medical College, etc., 8vo., pp. 381. New York: Wm. Wood & Co., 1880.

In *Our Mutual Friend*, Mr. Dickens describes the despair of the newly married Bella Wilfer, at the absurd directions of the cook-book: "Take a Salamander" or "throw in a handful of some unattainable substance;" and in a similar way the beginner in gynecology, away from the precise and definite ocular demonstration of the schools of to-day, must often feel bewildered about just how to do very simple matters, how to introduce a sponge-tent, how to wrap a probe with cotton, etc. We confess that after having wrapped many probes with cotton we still learned something valuable about it from reading Dr. Mundé's book.

The book fills a real space—meets a real want—really tells us how to do things, not simply when to do them, or to do them, but carefully, diffusely even, describes everything; for instance, just how a woman steps upon the gynecologist's table, and just how likely she is to shrink from doing it. The three hundred illustrations are necessary in such a work. Does a writer say, "Use Heburn's modification of Sims's speculum?" there on the page is its "counterfeit presentment." Does the practitioner wonder how to evert the rectum? turn to page 56, and see a finger everting it; the operator being evidently inside the patient, or else having taken her rectum into another room so as to evert it quietly. Does he shudder in perplexity about how to introduce his finger into the vagina, or in the stilted medical phraseology of the day to "practise indagation?" there on page 42 is a hand, in the attitude of a full-cocked Colt's revolver, pointing into space. All he has to do is to point his hand similarly, and slowly advance. Does he wonder how a woman looks on Dr. Chadwick's table? on page 28 he will see all he should, and probably more; and in many of the illustrations not only does one look at the human form divine, but gifted as it were with some magic power, one sees within the solid flesh the still more solid bone.

The wood-cuts are generally good, except the two remarkable ones, not original, on pages 78 and 79, which might be appropriately named "Clinging to the Rock," and "Afloat on a Dining-Table," but which are called respectively the correct and incorrect positions for examining with Sims's speculum.

The arrangement of Dr. Mundé's book is such as to facilitate reference. Part I., on Gynecological Examinations, embraces Verbal Examination, Methods of Local Examination, Positions for and Couches for Examination, and Examination without and by means of Instruments. Part II., on Minor Gynecological Manipulations and Applications, contains Catheterization, Dilatation of the Urethra, Injections of the Bladder, Applications of Medicinal Agents to Vagina and Cervix, Vaginal Tamponade, Applications to the Endometrium, Dilatation of Uterus, Curetting Uterine Cavity, Local Depletion, Injections into Cervix, Reposition of Displaced Uterus and Ovaries, Pessaries, Artificial Impregnation, Massage, Hypodermic Injection of Ergot, and the Gynecological Armamentarium.

It will be seen at a glance that the field is extensive, and it is admirably occupied by the author. Where verbal description is wanted, we find it full and clear. Where illustration would assist, it is apt. There appear to us to be very few topics neglected, and very few errors. The author seldom dogmatizes, but states the many ways of doing a thing without comment, only occasionally pausing to discourage the use of certain procedures, or to limit their applicability. We can scarcely imagine a more useful book of its kind, written as it is to find favor not only with the beginner, who knows nothing, but the practitioner of years who would willingly know more; and if the latter be disposed to cavil at times at its prolixity about details with which he himself is perfectly familiar, he must remember that it is on just such simple matters that the novice needs enlightenment, the book being both a primer and an encyclopædia of gynecological knowledge.

SOCIETY PROCEEDINGS.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, February 17, 1882.

George Ross, A.M., M.D., President, in the Chair.

Dr. Osler showed a series of specimens illustrating certain points in the pathology of atheroma of vessels.

1. *Atheromatous Plate and Ulcers on Arch of Aorta.*—The specimen was taken from a man æt. sixty-five, who died in the General Hospital about ten days after fracturing the head of the left femur. The death was somewhat sudden and unexpected. The friends would not permit the head to be opened. Nothing of special moment was found in the viscera; fat emboli were suspected, but none were found on careful examination of the lungs. The heart was normal; valves a little stiff. The anterior wall of the arch presented a flat plate, about ten by six cm., and from three to four times the thickness of the rest of the tube. The intima over this area was opaque, and presented irregular prominences. At one point, two cm. in front of innominate, there was an oval loss of substance eight by four mm., which led into a small atheromatous abscess, the contents of which had in great part escaped. The increased thickness of the wall was due to a layer of brownish-yellow firm caseous matter between the intima and media; in places this was five to six mm. in diameter; it was nowhere calcified. There was another spot of softening in it, which had not burst into the tube, but was separated by a thin brownish membrane. On squeezing from the outer side, a puriform fluid escaped. There were a few small spots of atheroma in the descending aorta. No satisfactory cause of death was found, and it seemed scarcely

likely that the bursting of such a small abscess would produce immediate death. Unfortunately, the mode of death was not known, as the patient was found dead by the night-nurse. Such a spot might form the starting-point of an aneurism, as in the next specimen. Whether any symptoms follow this condition, is not positively known; we certainly meet with these ulcers in many cases which, during life, have not afforded any evidence of their presence.

Dr. GIRDWOOD thought it not improbable that the bursting of the abscess, and discharge of its contents, caused death, though, of course, it was impossible to say in the absence of an examination of the brain. He asked whether there was a murmur. Dr. Osler could not say.

2. *Atheromatous Abscess and Aneurism of the Right Iliac Artery. General Atheroma.*—The case was that of an old woman, who died of cancer of the cardiac end of the stomach. She had dry gangrene of the toes of the right foot. The heart was in a state of brown atrophy, and the valves were stiff. The aorta presented numerous calcareous plates, and towards the bifurcation was firm and rigid. The intima had many smooth, brownish-yellow calcified patches, and there were four or five small atheromatous abscesses. The right iliac, at its origin, presented a firm, elastic tumor, the size of a walnut, which almost obliterated the lumen. When the vessel was opened, the tumor was seen to be an aneurismal sac, communicating by a small orifice, which was blocked with adherent clots. On section the sac was found filled with reddish thrombi in the lower, and pulpy atheromatous matter at the upper part. It was evidently a small atheromatous abscess converted into an aneurismal sac. The external iliac and femoral, with its branches, were removed, and the walls found to be thickened, and in places calcified. Near the popliteal, the lumen was greatly reduced, and an adherent thrombus almost obliterated the vessel. In several spots the calcified intima was elevated by a quantity of pulpy atheroma beneath it.

In connection with this specimen a microscopical section was shown of obliterating arteritis of the anterior tibial in a case of dry gangrene in an old man.

3. *Bizzozero's New (?) Blood Element and its relation to Thrombus Formation.*—In the case of extensive cancer of stomach in an old man there was an extraordinary condition of the aorta just above the bifurcation. There was tolerably advanced atheroma of the entire intima, patchy and in places calcified. Just above the bifurcation there was a grayish-white, irregular mass, five by three cm., somewhat flattened but projecting about one cm. from the intima, to which it was closely united. In the abdominal aorta there were six or eight smaller spots of a similar character attached to localized area of atheroma. The appearance when fresh was very suggestive of a neoplasm, and they were thought at first to be a secondary cancerous mass. On examination the large spot was found to be composed of closely set, small, colorless bodies, about one-third or one-fourth the size of red blood corpuscles, discoid, and with a uniform grayish stroma. They appeared to be identical with the individual elements of Schultze's *granule masses*, which are so common in the blood of some individuals. In Dr. Wood's case of aneurism (*vide infra*) the gray filaments on the walls were made up of precisely the same elements. A few colorless corpuscles and some fibrin fibrils also existed, but they were in trifling amount compared with the small elements. Dr. Osler remarked that these were the little bodies recently described by Prof. Bizzozero, of Turin, as a new blood element. But they had in reality long been known, having been described by Schultze in 1861. They occur in the drawn blood in the form of granular clumps, but he (Dr. O.), had shown, in a communication to the Royal Society, in 1874, that in the circulating blood the individual elements of the masses were isolated, and in the form of small discoids; a plate was passed round illustrating them as seen in the subcutaneous vessels of the young rat, which was the most favorable animal for the study of these bodies. In the case under consideration, these elements had apparently collected on an extensive area of atheroma, and had either multiplied there, or the mass had been formed by their gradual accretion. Bizzozero regards them as having an important influence on the development of fibrin (*Centralblatt f. d. Med. Wissenschaften*, Jan. 14, 1882).

Dr. OSLER presented the following specimens in comparative pathology:

1. *Bronchitis in a Calf—Purulent Bronchiectasy.*—The specimen was taken from a Galloway calf three months old, never very strong, and which had been troubled with a severe cough for over two months, and had become much emaciated. There was irregular fever, never more than 2° above the normal.

At the *post mortem*, the anterior lobes of both lungs were dark-colored, airless, and presented a remarkable condition of uniform distention of all the bronchi, with thick, tenacious pus. Even the finer tubes were dilated, and presented, beneath the pleura, a dendritic outline, with here and there a sacculated appearance. The intervening lung-tissue was of dark-red color, and collapsed. A section looked as if the tissue was thickly studded with small abscesses, but each one was only a distended bronchus, and with the probe-pointed scissors could be slit up to its farthest ramifications. There were no caseous masses, or areas of general solidification of the lung. The affection was most marked in the dependent parts of the lobes, the upper regions being free.

The thick creamy contents consisted of closely aggregated pus-cells, fatty *débris*, and a few epithelial elements. No trace of any strongyles. Microscopical sections showed the bronchial tubes thickened, infiltrated, and in many places the adjacent air-cells were filled with inflammatory products. Dr. Osler remarked that such a state of general distention of the bronchi might have been produced by a severe bronchitis in a delicate young animal, the copious secretion gravitating to the dependent parts. This appeared to be much more frequently the case in animals than in man.

2. *Glanders.*—The split head of a horse, showing the nasal fossæ and sinuses. The horse had been ill for several months, but was in pretty good condition, but had a chronic muco-purulent discharge from the nostrils. The specimen showed, (1) numerous ulcers, large and small, many of which could be seen from the external orifices. (2) Glanders tubercles in the form of isolated neoplasms on the Schneiderian membrane. They were thickly set in the upper part of the septum, and some were as large as beans. Many had begun to soften. (3) Diffuse infiltration of the mucosa with a grayish material; this was most evident in the frontal sinuses and in the antra, but it existed more or less over the turbinated bones. (4) Stellate cicatrices of healed ulcers. The trachea presented numerous nodules and a few ulcers, and the lungs contained some of the specific nodules of the disease. Liver, spleen, and kidneys were healthy. The cervical lymph glands were much swollen, and contained a few nodules. There was no cutaneous glanders (farcy).

Dr. GURD asked with reference to its degree of communicability, and whether many cases in man had been met with here.

The PRESIDENT believed that the liability of man to contagion from this disease was somewhat overrated; at least, there were many cases of glanders in horses, and yet instances of infection of grooms and others

were very rare. He had only seen one case, that of a groom who had taken charge of several glandered animals on board of a river steamer. The stench from them was very great, and he took the affection by inhalation of the poison.

Verminous Aneurism.—Portion of the arteria colica of a horse showing a small aneurismal dilatation, the size of an almond; the walls, thickened, covered with adherent thrombi, among which were five or six specimens of the *strongylus armatus*, or palisade worm. The parasite bores its way from the intestine, and penetrating the arteries, excites arteritis, with weakness of the wall, and dilatation and thrombosis in the lining membrane. It is a common affection in horses, and, according to Bollinger, is the most frequent cause of colic in these animals. He states that of one hundred horses afflicted with internal disease, forty are ill with colic; of any hundred diseased horses, forty have perished from colic; and among one hundred colic patients, eighty-seven recover, and thirteen die. No epizootic or sporadic affection in horses is so common, or has so many victims.

Aneurism of Thoracic Aorta; Perforation of Œsophagus.—Dr. C. A. Wood narrated the case. A woman aged fifty-five had been ailing for some days with dyspeptic symptoms. One night, on going to stool, she complained of feeling sick, but did not vomit; fell over and died in a few minutes. There had not been any apprehension of serious trouble, and nothing special had been elicited on examination of chest and abdomen. The *autopsy*, by Dr. Osler, revealed a large coagulum in the stomach, forming a mould of the organ. No source of the bleeding was detected until the œsophagus was dissected, when a small aneurismal tumor, the size of a billiard ball, was found between it and the aorta, about two inches above the cardia. The aorta presented in the lower thoracic portion a small punched-out orifice, the size of a five-cent piece, with a narrow zone of thickened translucent intima about it. This led directly into a small saccular dilatation of the *intima*, not larger than a marble, which had ruptures, and formed the main sac, spheroidal in shape, with walls composed of thickened *media* and *adventitia*. It contained fresh clots and thin mural thrombi; the perforation into the œsophagus was by a small orifice, which was plugged with clot. On the thrombi lining the sac there were curious branched thread-like filaments, strikingly marked against the dark-red background. These were composed of minute spherical bodies, identical with those found in the thrombus in the aorta of the case just described. There was no heart disease, and the aorta was not atheromatous, except in the zone just about the orifice. The trouble had probably originated in a localized atheromatous process, with softening, rupture, and subsequent dilatation. The case presented an additional feature of interest, inasmuch as the woman had been under observation four years before with symptoms of acute phthisis, but had, unexpectedly, made a complete recovery. The upper half of the right lung was firm, and contained much fibroid tissue, with several bronchiectatic cavities.

Dr. Girdwood remarked on the latency of many cases of aneurism and the varied symptoms produced by irritation or pressure. He narrated a case in point in which digestive troubles were for a long time the most prominent feature in a case of abdominal aneurism.

Dr. Mills asked if there was any difficulty in swallowing, and suggested that auscultation of the œsophagus might have given some information in such a case.

Dr. Wood stated that he had made a most careful examination, and had not been able to detect any abnormal physical signs in either chest or abdomen. He had not auscultated the gullet.

Ammonia Poisoning.—Dr. Arthur A. Browne related the case, and presented the stomach and œsophagus. The patient, a man aged fifty-five, had been in the habit of taking bromide of potassium after drinking bouts. His bottle was accidentally filled with strong liquor ammoniæ, and he gulped down a mouthful directly from it. Great pain was at once experienced, and bleeding from the stomach came on, and was profuse for about twelve hours. The vomiting was frequent, but after the bleeding ceased it only recurred when food of any kind was taken. The patient lived four days, and was sensible to the end. There was very slight affection of the mouth and fauces; not much tenderness over stomach; but the chief pain was referred to the chest. The amount swallowed could not be definitely determined. The *autopsy* showed great engorgement of the tissues in the course of the œsophagus and about the fundus of the stomach. The mucosa of the fauces and gullet was of a deep yellow-brown color, looking dry and burnt. The cardiac end of the stomach and a patch at the fundus were chiefly affected; the mucous membrane was greatly swollen, dark-yellow in color, and in places looked sloughy. There was deep congestion of the submucous and muscular layers in this region. The rest of the surface was unaffected. The epiglottis and larynx were injected, but the mucosa was not burnt.

The President said that he had been called to see this case shortly after the accident, and had seen the patient on several occasions with Dr. Browne. The points which struck him as most peculiar were the absence of laryngeal symptoms and the persistent pain in the chest.

Dr. Girdwood suggested that the greater affection of the fundus was due to the great volatility of the poison. In an instance of poisoning with caustic potash the pyloric end of the organ was chiefly involved, and a stricture occurred of which the patient died.

Clonic Spasm of the Psoas Muscle.—Dr. Lapthorn Smith exhibited a woman, aged thirty, with what he considered to be clonic contractions of the psoas and perhaps iliacus muscles of the left side. There were strong pulsations in the left inguinal and lumbar regions, fairly regular in rhythm, but varying in rapidity between ninety to one hundred and fifty in the minute and not synchronous with the pulse. They could be felt best when the patient was sitting on her haunches with the abdominal muscles relaxed. Pressure increased the force of the contraction, but the firmest possible compression controlled it. The movement began at the lumbar vertebræ and could be traced to the lesser trochanter of the femur. When acting strongly, a forcible, shock-like impulse was communicated to the hand. The side of the body was jarred and moved with each contraction. When recumbent, the left leg was moved but not flexed. The patient was hysterical and had been the subject of this affection for over eight years. Dr. Smith believes the contractions to be due to nerve discharges from unstable cell elements in a localized spot of the spinal cord.

Dr. Girdwood suggested that the contraction might be in the abdominal muscles. The patient was examined by the members, most of whom agreed with Dr. Smith as to the site of the contraction.

Medico-legal Case.—Dr. Girdwood read a paper on the Plantagenet murder case, in which David Prevost and Damage Brunet were arraigned for the murder of Pierre Brunet. The facts were briefly as follows: The murdered man, aged eighty-one, but strong and active, lived alone, his nearest neighbors being his second wife and a step-son, who lived together on a lot which he had given the son, on the condition of an annual payment of twenty dollars. On the death of the old man the land would be free of encumbrance. Damage Brunet

had repeatedly tried to sell the lot, but the accrued tax interfered. On Monday, September 20, 1880, the old man was last seen going towards a bush, one and a half miles distant from his house, where he was engaged in clearing. On Wednesday he was missed and a search was made, but the body was not found until three weeks after. It lay in a field, near where he was working, covered with twigs, the pockets turned inside out, and the contents gone. Decomposition was far advanced, and the head separated on attempting to move the body. About the time of the murder, David Prevost went to the shanties lumbering, but while there he behaved so strangely, talking of some dreadful deed which he had committed, and asking the men to pray with him, that he was sent home, where, shortly after, he was imprisoned for larceny. He then confessed that he and Damage Brunet had murdered the old man, having strangled him in his house and carried him to the field where he was found.

The points of interest chiefly dwelt upon by the author were the advanced state of decomposition in the short space of three weeks, and the plea of insanity raised in the case of David Prevost, who was uneducated and of a low, revolting type of countenance. There was no apparent motive why he should have committed the deed, other than the solicitation of his friend, and, perhaps, the gift of a small sum of money. Dr. Girdwood raised the question of his knowledge of the illegality of the act, and maintained that to constitute legal responsibility, there should be a knowledge of the illegality of the act. He argued that in the public schools instruction should be given concerning the different crimes, and the punishments attached to them.

Owing to the lateness of the hour, the discussion was postponed until the next meeting.

CORRESPONDENCE.

THE CULTIVATION OF MICROPHYTES AS BEARING UPON THE DOMESTIC ORIGIN OF YELLOW FEVER.

To the Editor of THE MEDICAL NEWS:

SIR: In a report to the Surgeon-General of the army upon the yellow fever epidemic of 1876, in Savannah, parts of which were published in the *American Journal of the Medical Sciences*, July, 1877, I expressed the belief that that particular outbreak was of domestic origin. This judgment I reached in opposition to my preconceived opinions, from considering what appeared to be facts irrespective of hypotheses. The contrary view was maintained by many—I may say by most—including respectable authorities; and stress was laid, sometimes by expression and sometimes by implication, upon the antagonism of my opinion with the prevalent belief in the germ theory of the origin of disease. The drift of feeling was that, the germ theory being probably true and not admitting within its provisions apparently spontaneous outbreaks, my observations were either inexact in themselves or incomplete as a series. I do not rehearse this to reopen a discussion on the Savannah epidemic. At this date no new facts properly authenticated can be produced, nor is it probable that believers in either view will change their minds as to what was the case in 1876. But I do think it important to invite attention to indications confirmatory of what I have expressed.

In a paper[1] that was read before the American Public Health Association, November 20, 1879, this reply was presented to those who, on hypothetical grounds, deny that a domestic origin may be attributed to yellow fever:

"But the germ theory in its integrity does not compel belief in an infinitely extended ancestry of germs, each identical with its predecessor and its successor, and each capable of exciting some specific disease immediately upon the victim coming within its range. With more confidence we may imagine an infinite variety of self-propagating germs, each set of which may gradually yield to adjacent influences, as is conspicuous in the cultivation of vegetation and is shadowed in animal life, and then suppose that with the metamorphosis induced by the surrounding conditions the yellow fever cause is gradually evolved. These presumed changes, although, perhaps, involving many generations of germ life, may easily be accomplished within the period of a single season, and would be developed with a rapidity proportionate to the propitiousness of the situation. If such a modification has occurred once, it may occur a thousand times. This view is perfectly consonant with the essence of the germ theory, and at the same time it is not inconsistent with the facts as I believe they are found in practice."

That the virulence of some germs may be mitigated, and that some disease-causes may be so far controlled or domesticated, as it were, as to be used as allies for the repulse of their more savage kin, the brilliant discoveries and practice of Pasteur, in the case of splenic fever, have placed beyond doubt.

I offer, parenthetically, the suggestion that the recognized mildness of some diseases towards the close of an epidemic may be explained by Pasteur's discovery that the disease-cause is weakened, not intensified, as we might suppose, by passing through the bodies of the sick; that is to say, in so far as the disease is propagated from case to case each generation of poison is weaker than its predecessor, requiring less resistance on the patient's part to overcome it.

Now, reverting to what Pasteur has demonstrated, that some disease-germs may be changed in degree towards one end of the scale, that is in the direction of harmlessness, there appears no logical obstacle to the modification, under auspicious circumstances, of originally innocent germs in the other direction, that is, towards malignancy. This, there is reason to believe, Grawitz, of Berlin, has demonstrated; although it is proper to say that a very recent paper by Koch throws doubt upon his procedure. But Grawitz's experiments appear to have been conducted with scientific precaution and care, and to show that from an innocent fungus one deadly to animal life may be cultivated. Whether that is absolutely certain or not, I make this note to insist, inasmuch as Pasteur has proved their mutability as a class, upon the increased possibility of the natural cultivation, under a torrid sun in the alkaline decomposing feculence of sewers, cesspools, and wharf-heads, of those microphytes to which yellow fever may be due.

Very truly yours,

ALFRED A. WOODHULL,
Major and Surgeon U. S. Army.

BROOKLYN, February 17, 1882.

KANSAS CITY.

(*From our Special Correspondent.*)

SPINA BIFIDA.—At the last meeting of the Jackson County Medical Society, an interesting case of hydrorachitis was exhibited by Dr. Lyman Berger. The case is worthy of note from the fact that after having, in vain, pursued several of the recognized modes of treatment, an apparently untoward accident gave a very satisfactory cure.

The important points in this case are as follows: A child of undeformed German parents, now five months

old, was born with a cleft spine, and a tumor of about three-quarters of an inch in diameter, situated over the last lumbar vertebra. During the first five weeks subsequent to birth, the tumor rapidly increased in size, until it was somewhat over two inches in diameter, and the overlaying skin became thin and translucent. At this time the child was put under treatment, and within the following six weeks five separate operations were from time to time performed, generally after the manner of the partial or nearly complete evacuation of the sac by aspiration and the injection of tincture of iodine, with the after-treatment of pressure by means of the cupped sponge, or, as was used after the last operation, of a small chamois skin covered hernia pad. None of these operations were successful, the sac refilling, more or less rapidly, after each one of them. Upon the day following the last operation, while the dressings were being removed preparatory to adjusting a smaller-sized (⅞ by 1¼ inch) hernia pad, the sac ruptured and completely emptied itself. The pad was quickly adjusted to the new pouch-like depression in the tumor, and held in place by adhesive strips, so that it was perfectly immovable. The sudden evacuation of the contents of the tumor brought about a condition of collapse, and no small amount of attention was required to keep the child alive; but after a time, however, the system rallied, and the parts seemed to accommodate themselves to the loss of the fluid. The only apparent impression left upon the brain by so great a loss of cerebro-spinal fluid being a depression in the anterior fontanel. For two days after the occurrence of the accident there was oozing of the spinal fluid from the point of rupture, but after this time none could be detected. At the expiration of a week the opening was found to be closed and to be healing by granulation, and the walls of the sac to be adherent. The tumor at this time had the appearance of a concave flattened disk, of from 2 to 2½ inches in diameter, depressed in the centre, and lying flat upon the back. There existed a circular space of about an half inch in diameter at the centre of the pouch-like depression in the flattened tumor, which had a thickened, cutaneous covering, and beneath which could be distinctly felt the cerebro-spinal fluid. This circular space, at the time the case was reported, was seen to have been gradually growing smaller, and it was anticipated that eventually the space would be closed, or so filled in with thickened tissue as to give a very fair result.

VIENNA.

(From our Special Correspondent.)

Hyperemesis in Pregnancy.—Dr. Carl Ritter Braun von Fernwald was recently called in consultation to a distant part of Austrian-Hungary, to a lady of rank, suffering from hyperemesis in pregnancy. He found the patient in the fifth month of pregnancy, very much emaciated from the totally uncontrollable vomiting. The attending physician was urgent in advising the immediate induction of premature labor. Dr. Braun, however, did not approve the suggestion, but caused the vaginal portion of the cervix to be freely bathed in a ten-per-cent. solution of nitrate of silver in water. Five minutes later the vaginal portion of the cervix was well dried to prevent further corrosive action. The vomiting ceased at once, and one hour later the patient asked for a veal cutlet, which she ate with great relish and retained. There has been no recurrence of the vomiting. Dr. Braun is of the opinion that, in general, hyperemesis in pregnancy should not be regarded as an indication for the induction of premature labor, for the reason that he has frequently seen this operation result in death, while he has never seen a case of fatal hyperemesis occurring in a pregnant woman.

For Hysterical Convulsions during pregnancy, a very frequent and annoying occurrence among Viennese women, Dr. Braun uses, with great success, the following prescription:

℞.	Asafœtida, ...	5.
	Camphor, ...	.5
	Aqu. Font., ...	200
	Vitelli Ovi., ...	No. 2
	D. S. For two clysters.	

The Public Health.—For the week ending February 18, the deaths from small-pox, not before reported, were as follows: Chicago, 25; Pittsburg, 22; St. Louis, 9; New Orleans, 4; Omaha, Neb., 2; Richmond, Va., 5; and Brooklyn and San Francisco, each 1. Diphtheria caused in the same week 23 deaths in Brooklyn; 8 in Detroit; 7 in Chicago; 4 each in St. Louis and San Francisco; 3 in Buffalo; and 2 in Pittsburg. For the same period the deaths from typhoid fever were 12 in Chicago; 8 in Buffalo; 4 in San Francisco; 3 in Pittsburg; 2 each, in New Orleans, St. Louis, and Richmond, and 1 in Brooklyn. At the present time Vicksburg, Miss., is suffering from an epidemic of measles; chicken-pox is also said to be prevalent. There were 6 deaths from measles in Chicago. Scarlet fever is still very prevalent in Brooklyn, 30 deaths being reported in the week. Buffalo in the same week had from this cause 12 deaths; St. Louis, 7; San Francisco, 4; and Detroit, 3. With the exception just noted, neither measles, whooping-cough, nor cerebro-spinal meningitis are prevalent in any of the above-named places.

In the northern and western cities, and in San Francisco, pulmonary disease figures prominently in the weekly bills of mortality. Consumption was proportionately more fatal in New Orleans than in most of our large northern cities, and in San Francisco the mortality from this cause (16) was greater than from any other cause except pneumonia (25).

The mortality reports for the week ending February 25, so far as received, show a marked falling off in the number of deaths, from small-pox, particularly noticeable in Philadelphia, where the deaths decreased from 17 to 7. The numbers reported are as follows: Chicago, 35; Cincinnati, 25; New York, 12; Philadelphia, 7; Pittsburg, 11; Richmond, Va., 4; Memphis, 21; Boston, 1; and in Richmond, Va., 1 death from varioloid. At Pittsburg there were 60; at Milwaukee, 1; and at Richmond, Va., 21 new cases of small-pox and varioloid reported. From cerebro-spinal meningitis in Boston, Cincinnati, and Augusta, 1 death each; and in Philadelphia, Pittsburg, and Chicago, 2 each is the record of the week. Diphtheria is still very prevalent in Boston, 14 deaths being reported, the same number as occurred the preceding week. There were 12 deaths in Philadelphia; 9 in Chicago; 2 each in District of Columbia, Wheeling, Va., and Dayton, O.; and 1 each in Pittsburg, Richmond, Va., and Milwaukee. There are no reports of excessive mortality from scarlet fever. Philadelphia reports 7 deaths from this cause; Chicago, 7; Pittsburg, 5; Providence, R. I., 3; Milwaukee, 3; and Cincinnati and the District of Columbia, each 1. The deaths from typhoid fever are as follows: Philadelphia, 16; Pittsburg, 15; Chicago, 7; Boston, 5; District of Columbia, 4; Indianapolis, 3; Cincinnati, Wilmington, Del., and Louisville, each 2; and Providence, R. I., Richmond, Va., Wheeling, W. Va., Savannah, and Charleston, each 1. From seventeen prominent places throughout the country there are reported in the aggregate only 8 deaths from whooping-cough and 25 from croup, 8 of the latter occurring in Chicago.

Health of Hudson Co., N. J.—Population for 1882 estimated at 394,402. Deaths for month of January, 558. The mortality for January has been exceptionally

great this year. Consumption heads the list with 75 deaths. The deaths from other prominent diseases were as follows: Pneumonia, 59; small-pox, 49; diphtheria, 35; bronchitis, 25; scarlet fever, 26; croup, 22; malarial fever, 19, and typhoid fever, 12. It is a noticeable fact that nearly one-half of all the deaths were of children under five years of age. Diseases of the respiratory organs caused about one-third of the total mortality. Small-pox is charged with 8.78 per cent. of the whole number of deaths for the month.

HEALTH IN MICHIGAN.—The Bulletin of the State Board of Health for the week ending Feburary 18, 1882, states that scarlet fever and tonsillitis have considerably increased, and that erysipelas, consumption, and neuralgia have considerably decreased in area of prevalence.

Diphtheria was reported present during the week ending February 18, and since, at twenty-one places; scarlet fever, at eighteen places; measles, at six places; and small-pox, at seven places in all, as follows: at Parkville, St. Joseph County (one case, convalescent), February 15; at Grand Rapids, Escanaba, and Detroit, February 18; at Stanton, Montcalm County (one case), February 20; at Spalding, Menominee County (nine cases, one new), February 21; among the Indians at Indiantown, near Spalding (eight cases), February 21, 1882, and twenty-two deaths to that date..

BIRTHS IN PARIS.—From the 20th to the 26th of January, 1882, there were 1353 births, distributed as follows: Males—legitimate, 491; illegitimate, 202; total, 693. Females—legitimate, 480; illegitimate, 180; total, 660.

During the same period there were 86 children born dead, or dying before registration. Of these there were 30 legitimate males, and 9 illegitimate; total, 39; and 32 legitimate females, and 15 illegitimate; total, 47.

THE GRAND PRIX LECAZE.—The Paris Academy of Sciences has conferred on Prof. BROWN-SEQUARD the distinguished honor of the Grand Prix Lecaze. This prize, which is of the value of 10,000 francs, is only given in recognition of a life-long devotion to physiological science which has resulted in important discoveries. The previous recipients have been Chauveau, Marey, and Dareste.

THE UNIVERSITY OF VIRGINIA.—A correspondent of the *New Orleans Medical and Surgical Journal* writes as follows of the University of Virginia: "Had our Southern neighbors no other boast, they might well be proud of that University.

"Let us see what per cent. of each class is graduated there. I have accurate data for two years only. In 1878–79 there were 53 men in the medical class; 48 of these applied for graduation, and 21 alone were successful. In 1879–80 there were 46 in the class; 31 applied and 10 only graduated. I had almost as soon be one of those 10 as a survivor of the 600 at Balaklava. Can we wonder at the small classes there? But the men of that faculty prefer a small class to a large one, where the pen which titles a fool tells a lie at every stroke."

NEW YORK NIGHT MEDICAL SERVICE.—Dr. William A. Ewing, Superintendent of the New York Night Medical Service, has submitted to the Board of Health a report of the operations of the bureau during the sixteen months of its existence, from September 1, 1880, when the act of Legislature was obtained, until January 1, 1882. It appears that in all, 573 calls have been made during the period above specified. These were distributed among 132 physicians out of the 450 whose names appear upon the roll. It is noticed as a curious fact that the tenth precinct, embracing a large tenement-house district lying east of the Bowery, has afforded more calls upon the service than any quarter of corresponding area in the city. The majority of cases treated have been of a very urgent description, comprising, for illustration, 57 night attacks of croup, 28 of pneumonia, 10 of pleurisy, 55 of confinement, 2 of gunshot wounds, 11 fractures and dislocations, 15 suicides, and 3 of accidental poisoning. Of all the cases in which calls were made, only 19 were able to pay the fee specified by law, and in the remaining 554 the appropriation was called upon.

HYGIENE IN THE PUBLIC SCHOOLS OF PARIS.—According to a decree of the Minister of Public Instruction, a commission has been formed whose duties are to study the relations between the methods of instruction and the hygiene of the pupils, receiving authority to make whatever inspection and examination they may deem necessary, and to report their results to the Superior Council.

SANITARY CONVENTION AT GREENVILLE, MICHIGAN.—In accordance with invitation received from citizens of Greenville, arrangements have been made by a local committee of citizens acting with a committee of the State Board of Health, to hold a Sanitary Convention in the city of Greenville, Michigan, on Tuesday and Wednesday, April 11 and 12, 1882. At each session of the convention there will be addresses or papers on subjects of general interest pertaining to public health, each paper to be followed by a discussion of the subject treated.

The officers chosen are as follows: President, Rev. J. L. Patton, of Greenville; Vice-Presidents, Hon. E. H. Stanton, of Ionia; Rev. A. A. Brown, of Greenville; Hon. H. H. Hinds, of Stanton; Charles P. Bigelow, M.D., of Big Rapids; Hon. J. P. Shoemaker, of Amsden, and Hon. R. C. Miller, of Greenville; Secretary, Charles S. Sheldon, M.D., of Greenville.

Manufacturers of sanitary apparatus or appliances, and dealers in the same, or in any article conducive to health, are invited to send samples of their wares for exhibition at this convention. Judges will be appointed to examine the various articles on exhibition, and certificates of merit will be awarded to such articles as are deemed worthy.

Among the subjects which it is desired to have presented and discussed are the following:

1. The Prevention and Restriction of Small-pox, Diphtheria, and Scarlet Fever.
2. The Present and Prospective Water-supply of Greenville.
3. The Disposal of Decomposing Organic Matter.
4. Pure Air; Why we should have it, and How we shall get it.
5. School Hygiene.
6. The Relation of the Newspaper Press to Sanitary Reform.

SPREADING OF YELLOW FEVER BY RAILROAD CARS.—In order to prevent the spread of yellow fever by means of railroad cars, etc., the Pullman Southern Car Company adopted the following precautions during the late epidemic, as shown in the Report of their Superintendent to the Illinois State Board of Health, from which the following extract is made:

All our cars were thoroughly disinfected at *every terminus of our lines*, and pure carbolic acid was exposed in open vessels in every car while *en route*. At terminal points every car was thoroughly cleaned—all bedding, seats, carpets, and, in fact, everything movable in the car, were taken out, whipped, brushed, and then fumigated in a close room with sulphur. Each car was scrubbed inside and out, and then closed and

fumigated with sulphur. After this process with car and equipments, they were both exposed to the open air for several hours, carefully dusted, and both car and equipments liberally sprinkled with carbolic acid. Carbolic acid was put in each spittoon on every car running into or through any infected district five or six times during each day or night. All cars were thoroughly ventilated while *en route*, by open doors, windows, and deck sash.

As soon as the disease was declared epidemic in New Orleans, Memphis, and other points, our cars were withdrawn, as in the case of the lines from New Orleans to Chicago and St. Louis, from Louisville to Memphis and Little Rock, and from Cincinnati to New Orleans, *via* Montgomery. We had one line of sleepers only that continued unbroken during the entire epidemic—the line from New Orleans to Cincinnati *via* Milan. On this line all cars were treated at each terminal point and *en route* as above indicated.

During the entire course of the epidemic we did not have a single case reported to us of yellow fever occurring from any *supposed infection* from our cars; and in *every instance* when any person coming from any infected district was taken sick on one of our cars, *not only the person*, but the *mattress, pillows, blankets, and sheets as well, were removed at the first station, and all bedding and material thus removed was invariably destroyed—in no instance was any portion of it ever returned to a car.*

We do not know of a single case, *nor do we believe one can be found*, of yellow fever developing itself on any of our cars, *except in persons coming north from infected districts*, and in whose system, beyond a doubt, the germs of the disease were implanted before they undertook the journey. In every case of this kind (and they were very few), the persons, and everything movable in the car, with which they had come in contact, were removed from the car as above described.—*Chicago Med. Journ. and Exam.*, Nov., 1881.

The Registration of Clinical Thermometers.—We have recently received the first Annual Report of Leonard Waldo, the astronomer in charge of the Horological and Thermometric Bureaus of the Winchester Observatory of Yale College, and have found it of so much interest and importance to physicians that we desire to call especial attention to it.

Many do not know the fact that in our own country they can have their thermometers tested; and quite as many, perhaps, are not aware of the pressing importance there is for such a test. Yet Mr. Waldo states that fifty of the thermometers tested during the year had errors of over 1½°; and he states, and we believe from some experience he is right, that "there is little doubt that the great majority of physicians' thermometers now in use in the United States are from 1½° to 2° too high in their indications!" Especially will such errors be marked in newly-made instruments, and the Observatory offers to seal up any ungraduated instrument sent to them, and after a year to return them to the instrument makers, with a certificate. They can afterwards be graduated, and then tested and certified as to their accuracy before being sold.

We are glad to see that during the year as many as 1667 thermometers for clinical and physiological use were tested—a very favorable showing as compared with the Kew Observatory (England) numbers, which were 1439 in 1875, and 3405 in 1879.

The regulations are very simple. The thermometer, which should be numbered, or otherwise designated, must be carefully packed and forwarded to the Observatory by express or by mail, prepaid, of course, and with fifty cents, the very moderate charge for such careful testing. After about three days they are returned with a numbered certificate giving the error in tenths of a degree for each 5° of the scale. Hospitals or individuals can make arrangement for systematic examinations at stated intervals of all their instruments, a necessary precaution to ensure continued accuracy. In fact, the Observatory, as in fine watches, so in thermometers, is striving not only to give us the exact errors of our instruments, but by a proper stimulus to the makers of both to foster the production of better instruments. How needful that is we have already stated, and an error of 1°, or even of 2°, is so probable in unregistered instruments as to throw discredit on all such. We feel bound, therefore, to urge our readers to buy only those that have been registered, and that are reasonably free from error, say with a maximum error of $\frac{5}{10}$°; and if they have already bought such uncertified instruments to forward them at once for test and certificate. How successful, also, the stimulus has been even a year shows; for while in June, 1880, four-fifths of all thermometers received from seven makers were in error over ⅓°, and two per cent. of over 1°. in April and May, 1881, four-fifths of all thermometers sent had errors less than $\frac{3}{10}$°. The standard of comparison used is within about 0.03° centigrade of perfection.

Medical School of Glasgow.—The class lists for the present session show that the number of students enrolled in the several medical schools is 863. Of these, 63 are attending science lectures, without the intention of entering the medical profession, leaving 800 *bona fide* students of medicine in Glasgow.

The Importance of the Coccyx in the Arab Anatomy.—Some curious facts are to be found in Bertherand's work on *Medicine in Algiers* as to the importance attached by the Arabs to the coccyx in relation to the future state. They designated this bone *Adeum tehoutehou*, the first word meaning bone, the second, a phonetic imitation of the sounds produced by the intestinal gases passing the anus. Mohammed has said that all the bones of the body are consumed in the ground, with the exception of one, the coccyx; and that this bone, the first created by the Deity for the construction of each skeleton, is the only one which resists all the causes of destruction, in order to serve at the judgment day for the rebuilding of each body. The rain of forty days, which will precede this great day, will fertilize all the coccyges, as osseous germs destined to reproduce all the other parts of the body in the same way as the seed which contains within it all the elements of the plant to which it will give birth.—*L' Union Méd.*, Jan. 21, 1882.

Guy's Hospital.—The managers of the nursing system, so strenuously upheld by the governing body of Guy's Hospital, are at least unfortunate beyond all precedent. The last nursing misadventure, resulting in the death of one of the patients in Guy's Hospital, appears to have arisen immediately from the disregard, by the ward-sister, of one of the ordinary rules in the management of the wards, namely, keeping all the poisons in the poison-cupboard. In each ward, there is a poison-cupboard, where all poisons are kept. In the present instance, the sister had neglected this necessary measure of safety, and left a basket on the table, in the middle of the ward, containing four packets, each of ten grains of morphia. A night-nurse came on duty in the evening, was told nothing of the powders by the sister, and mistook them for quinine powders. Why were the powders, of forty grains of morphia, enough to kill forty people, not placed in the poison-cupboard? For this, the ward-sister is, we presume, responsible. The nurse who gave the powders is responsible, in a less degree, for not having noticed

the poison-card lying among them. The dispenser would also have acted, to say the least of it, with more discretion, had he labelled each powder, sufficient as it was to destroy ten people, with a poison label. We cannot, however, approve the practice, which was going on, of allowing the ward-sister to prepare the solutions of such large doses of poison. Where it is necessary to employ poisons in such quantities, special precautions should be used. In the unfortunate case in question, the reverse seems to have taken place.—*British Med. Journ.*, Jan. 14, 1882.

PRISMATIC MIRROR FOR RHINOSCOPIC EXAMINATION.—At the meeting of the Société de Biologie on the 8th of December, M. GELLÉ presented a prismatic mirror for rhinoscopic examination, which has the advantage of presenting the image in the true proportions, and not distorted, as in the plane mirror. It is also extremely easy to introduce and gives a very distinct and well-defined image.—*Revue Mens. de Laryngologie, D'Otologie et de Rhinoscopie*, Jan. 1, 1882.

CLAUDE BERNARD.—The Municipal Council of Villefranche (Rhône) decided at their last meeting to erect a statute to the memory of Claude Bernard, in the place which already bears his name.

PERSONAL.—The dignity of State Chancellor has been conferred by the Emperor of Austria on Dr. Alexander Rollet, Professor of Physiology in the University of Gratz, in recognition of his long services in the cause of science.

OBITUARY.

ROBERT BRIDGES, M.D., Emeritus Professor of Chemistry in the Philadelphia College of Pharmacy, and one of its trustees, died at his residence in this city, February 20, 1882, near the close of his seventy-sixth year. He was born in Philadelphia, March 5, 1806.

His general education was concluded at Dickinson College, Carlisle, Pa., and he was graduated from the Medical Department of the University of Pennsylvania, March, 1828.

During many years he was the assistant of the Professor of Chemistry, Dr. Franklin Bache, in the Philadelphia College of Pharmacy, and succeeded him in the chair in 1842. His last course of instruction was delivered in 1879, when failing health induced him to retire, after thirty-seven years' faithful and efficient service.

After the death of Dr. Franklin Bache in 1864, he took his place in editing Wood and Bache's *Dispensatory*. He was assistant editor of, and contributor to, the *American Journal of Pharmacy*, and edited the reprints of Graham's *Chemistry*, Fowne's *Chemistry*, and Attfield's *General Medical and Pharmaceutical Chemistry*. He was a member of the Committee of Revision and Publication of the *Pharmacopœia of the United States*, in 1860 and 1870; a councillor of the American Philosophical Society; and a member of the Academy of Natural Sciences, of Philadelphia, from January, 1835. He was a Vice-President of the Society during fourteen years, and President for the year 1865, and declined re-election. He served the Academy as Librarian, as Corresponding Secretary, and as a member of its Publication Committee during twenty-four years.

He was elected a Fellow of the College of Physicians of Philadelphia, July, 1842, and held the office of Librarian during several years.

His learning was extensive, accurate, and varied, and among naturalists and medical men he was well known by reputation throughout the country. He was remarkably modest, unobtrusive; but never failed to win the kind and respectful consideration of all who became acquainted with him. His conduct throughout life was characterized by good sense, benevolence, and rigid probity under all circumstances. His firm yet quiet ways shed a salutary influence on the prosperity of the several institutions in which he was interested. His services to the Philadelphia College of Pharmacy and to the Academy of Natural Sciences, of Philadelphia, must be long remembered.

NOTES AND QUERIES.

A REFERENCE IN CICERO TO DISSECTION.

To the Editor of THE MEDICAL NEWS.

SIR: Few actual statements are made by ancient authors, even by the medical writers, as to the prevalence of dissection. Here and there an allusion to the custom is met with, which by the very indirectness of statement become the stronger proof that dissection was practised to a greater or less extent. Hence, we feel that no apology is needed for quoting the following passage from Cicero's *Tusculan Disputations*, Bk. I., Ch. XX., to which our attention was recently directed by Mr. W. E. Foster, the accomplished librarian of the Providence Public Library.

Speaking of our bodily senses, he says, "Neque enim est ullus sensus in corpore, sed ut non physici solum docent verum etiam medici qui ista aperta et patefacta viderunt, viæ quasi quædam sunt ad oculos ad aures ad nares a sede animi perforatæ," or translating it somewhat freely, "Nor is there any perception in the body itself, but, as not only naturalists teach us, but also doctors *who see these things uncovered and laid open*, there are, as it were, ways made (perforated) from the seat of the soul to the eyes, the ears, and the nose."

Cannot some of our scholarly readers furnish us with other similar allusions?

I am, sir, yours faithfully,

WILLIAM W. KEEN, M.D.

PHILADELPHIA, March 1, 1882.

CONVERSATION IN A DOCTOR'S OFFICE.

Miserable Old Woman.—"My daughter is married to Barney McMunns, and he gives her bad treatment, and abuse, and hardship—"

"And *McMunns, he licks her?*" puts in the doctor.

"Yes, and indeed he does," the old woman mutters.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 21, TO FEBRUARY 27, 1882.

POPE, B. F., *Captain and Assistant Surgeon.*—Relieved from duty in Department of Dakota and to report in person to the Surgeon-General for duty in his office.—*S. O. 42, A. G. O., February 21, 1882.*

MOFFATT, PETER, *Captain and Assistant Surgeon.*—Relieved from duty at Camp Spokane, Washington Territory, to proceed to Fort Coeur d'Alene, Idaho, and relieve Assistant Surgeon Spencer from duty at that post.—*S. O. 20, Department of the Columbia, February 11, 1882.*

FINLEY, J. A., *Captain and Assistant Surgeon.*—Fort Adams, Rhode Island. Granted leave of absence for one month.—*S. O. 29, Department of the East, February 20, 1882.*

SPENCER, WM. G., *Captain and Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for an extension of one month to Division Headquarters, and for an extension of four months to the Adjutant-General of the Army.—*S. O. 19, Department of the Columbia, February 10, 1882.*

RAYMOND, H. I., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at the Presidio of San Francisco and assigned to duty at Alcatraz Island, California.—*S. O. 28, Military Division of the Pacific and Department of California, February 15, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XL. SATURDAY, MARCH 11, 1882. NO. 10.

ORIGINAL LECTURES.

CLINICAL REMARKS ON FACIAL NEURALGIA, TREATED BY NEURECTOMY.

Delivered at the Orthopedic Hospital and Infirmary for Nervous Diseases, Philadelphia.

BY S. WEIR MITCHELL, M.D.,
PHYSICIAN TO THE INFIRMARY.

(Reported by GUY HINSDALE, M.D.)

GENTLEMEN: On the 29th of April, 1881, Ann D. came to this clinic suffering from facial neuralgia. She is forty-three years of age, and has been employed in housekeeping. For the last fifteen years she has lived in New Jersey and has enjoyed comparatively good health until three years ago, when a dysmenorrhœa, which had always been severe, became greatly exaggerated. In the summer of 1876 she had, without known cause, her first attack of facial neuralgia. The pain began in the lower jaw upon the left side, and finally extended so as to involve, in turn, other nerve branches on that side of the face. This attack lasted for six weeks. There have been since then several distinct onslaughts of neuralgia, each of them longer and more severe than those which preceded.

When she applied here her condition was one of absolute health, save as regards the maxillary pain and the uterine troubles, which latter seemed of late, however, to have been less annoying. The menstrual flow did not appear to bear any causal relation to the neuralgia, nor, when the pain was present, did it seem to be increased during menstruation.

The facial pain occurred every few minutes, day and night, and lasted a variable time, but not over two or three minutes. At first it began at a point in the jaw at, or near to, the mental foramen, but soon spread to the second and, finally, to the first branch of the fifth nerve. It was increased or caused by mastication, by deglutition, by talking, and by exposure to cold air. I could find no point of the face or mouth where firm pressure would either cause or inhibit the pain, neither was the stomach responsible; nor yet the teeth, most of which had, as usual in these cases, been relentlessly drawn.

In every such case as this one, where clearly no obvious local cause of pain can be made out, we are forced back upon two sets of measures—an effort to relieve the general nutritive defects which cause pain, and with this, or failing in this, a course of what is always more or less experimental therapeutics, that is, the use in turn of the various drugs like quinia, gelsemium, aconite, veratria, croton-chloral, and morphia—agents which alter the sensorial centres or the conductors in some such way as to lessen pain, and sometimes to do away with the cause of pain. It is hard to say succinctly more than this of these means, but, whatever be their value, it is increased or their use in some cases made needless by a long and thoroughly systematic effort to lift the general health above that level at which pain is one of the many evil probabilities. But these means had, in this instance, failed, and the various drugs used in neuralgia had had no better fortune, while, happily, my patient had escaped the habitual use of morphia.

I was unwilling to resort to the knife without a full trial of galvanism, which, in many supra-orbital neuralgias, is a most valuable agent, and, in some cases, is competent to effect absolute cures. In others, it merely relieves, but I have seen cases in which, although section of the nerve had failed, frequent and long use of galvanism afterwards triumphed.

Our patient was therefore put in bed, ordered to speak as little as possible, and was fed with food which demands no use of the teeth. Galvanism was used thrice a day for half an hour each time, the current being just enough to be distintly felt, since it is usual to find that more severe applications, save in the case of deep-seated nerves, do not answer as well as these milder currents. For a week the current was peripheral; then for a week we reversed it. If you were to ask why this was done, I should answer that, in my experience, it is sometimes indifferent as to what direction the current takes, but that sometimes it is not, and that nothing but a therapeutic experiment will decide the matter. In this present case galvanism proved utterly useless, and I was forced to the last resort of defeated therapeutics—the surgeon's knife.

Dr. T. G. Morton, one of the surgeons to this hospital, operated on the 31st day of May, 1881, entering the inferior maxillary canal with a small trephine at the point A of the diagram. In accordance with my request, the nerve was stretched, and then a half-inch exsected. I wished, also, to pull on the peripheral end so as after section to tear away as much of it as possible, but this was not done.

My desire to destroy so much of the nerve arose from a but too large knowledge of the ease with which cut nerves reunite. There was a wonderful illustration of this repair of nerves in a case of painful neuroma of the skin,[1] for the relief of which the late Dr. Maury exsected a portion of the nerves of the brachial plexus. Although the pain in that case was relieved for several months, within a year it became violent, and two years later was as severe as before. At the autopsy, six and a half years after the operation, the man being eighty-three years of age, the cut ends of the brachial plexus were found to have completely reunited. The connecting band was an inch and a half in length, remarkably strong and thick. This is a most notable fact, for while repair is rapid in the young, and very, very rapid in young animals, it has been generally supposed that the nerve ends would not reunite in old subjects.

It is important, therefore, to be careful to remove a large piece of the nerve, and, perhaps, it is almost as well simply to stretch the nerve as to cut out a piece of it. There is, in fact, no way, as yet tried, to prevent the extremities from reuniting, even doubling the ends over and pinning them back having failed in my experience. I have known cases where neither the second nor even the third division of a nerve has precluded the re-uniting of the ends. There is another case of mine on record where from one to three inches of the nerve was removed three times in succession, but where complete restoration took place. The fact that the inferior maxillary nerve runs in a canal, offers a better chance of permanent isolation of the peripheral end, and should I again have occasion to divide this nerve, I would make an effort to block the canal. I think this might readily be done by dissecting up a piece of

[1] Painful Neuroma of the Skin. Duhring. Amer. Journ. Med. Sciences, Oct., 1881.

the periosteum, and filling with it the bony canal, or by using carbolized sponge in the same manner.

When it becomes desirable to think of nerve-section or stretching, it is well to have a clear idea of why we are to resort to an operation. A distinct reason for it exists when it seems probable that the irritative cause lies in the periphery, and may, by operation, be cut off from the sensorium, which it disturbs; but also in cases where the cause is dubious or central alone, there may yet be two reasons for a section: First, because section or stretching in some way reacts on the centre so as to lessen its pain-making capacity; and, second, because in most old neuralgias of plainly central birth, the peripheral skin territories become sensitive, and are then easily played upon by external influences which in turn exasperate the abnormal centre and produce incessant attacks of pain.

It is well, also, to know in what nerve-filament the pain first started, since, in any view, that is the nerve to stretch. In the present case the pain had extended widely, in accordance with a law which seems to govern such cases—a law of diffusion of sensitiveness. At first one group of ganglia suffers, and then, as if the heightened capacity to cause pain were contagious, it is propagated to others, until at first near and then distant groups of cells are what I like to call sensitized, much as is seen in another fashion in tetanus.

It is my custom in all neuralgias to ask what causes pain and what lessens it. In a large number of cases, I am told that exposure to cold will bring on or increase an attack. Why cold air should have this effect, why it should be more hostile than heat, I cannot say. Nothing in medicine is, however, more sure than that, in certain maladies, the surfaces of the body acquire an increase of susceptibility to cold, and that a cool draught of air is competent to awaken or cause pain, as it is not in health. I showed years ago that in healthy birds, if we subject the naked skin to sudden chill we may cause the most remarkable phenomena in the way of convulsions or sleep, but in normal man, only the interior of the outer ear is able, on exposure to abrupt changes of temperature, to give us like phenomena. When, however, the centres have been irritated by disease, we seem to acquire an increased tendency to respond to atmospheric changes, so that in neuralgia, rheumatism, sclerosis, and the like, we become responsive in some way to impressions which are without notable influence on the healthy frame.

The period of time required for an abrupt cooling of the skin to occasion pain or other phenomena is another matter for thought. In some very sensitive cases a few moments suffice; in others the result follows after much longer periods. In birds, the vertiginous symptoms which follow the application of cold to limited skin-spaces require a certain length of time—from two to ten minutes. You will find, as a rule, in nearly all old neuralgias, wherever situated, that motion of parts concerned, and even of parts physiologically related to them will cause or increase the pain. In sciatic neuralgia, especially of neuritic or rheumatic birth, there is an obvious mechanical explanation of this in the pinching of the tender nerve, and it will be found that the effort of defecation and, more rarely, of urination, give rise to like results. In facial neuralgias the explanation is less easy, since in any fifth-nerve neuralgia, but most notably in that of the second and third branches, talking, chewing, laughing, and even deglutition cause or increase the pain. In these extreme cases, any sensation about the face, as a rough touch, or gentle friction, may be equally able to effect a like result; so that perhaps it is the awakening of the normal sensations which in all cases accompany physiological motor activities, which in some way arouses the morbid pain-making capacities of a hyperæsthetic sensorium. At all events these facts are found only in old and tenacious neuralgias. The pain is capable of being reproduced by almost any ordinary influence affecting the skin and also by almost any facial motor activity. You will see now and then cases in which severe but transient pain arises in certain people whenever they are abruptly exposed to great cold or to damp and cold.

Also, it is worth knowing that the steady use of moderate, stabile currents over and through the exit points of the fifth nerve is competent to relieve this condition; but in this and in the early stage of any facial neuralgia the first thing to think of is the patient's general condition. Cod-liver oil, tonics, and change of climate are of more value than all the violent drugs to which hasty therapeutists, driven by a sufferer impatient of pain, are apt to resort.

I wish to say a word about the teeth. In any neuralgia, have them looked over carefully by an expert, and let him not neglect to ascertain if there be a catarrhal trouble of the antrum; but never draw a sound tooth, or even a filled tooth, on no more evidence than the presence of a neuralgia. Bad teeth are rare causes of grave and persistent neuralgia.

When seeing many neuralgic cases, you will observe that the attacks come, by preference, at certain times of the day or night. For this there must be some distinct reason; but, as yet, the subject has been insufficiently studied, and regularity of attack is apt, without other reason, to induce the belief in a malarial cause; and since, in all fifth-nerve neuralgias especially, quinia is often a good remedy, the triumph of this drug is apt to be regarded as a fair confirmation of a theory which is certainly false in most instances.

As a rule, with many exceptions, fifth-nerve neuralgias are prone to recur early in the day or before noon, and sciatica to be worst at night, even if the patient be constantly in bed.

FIG. 1.

Shows the area of complete anæsthesia, surrounded by the zone of partial anæsthesia. The dotted lines indicate the corresponding areas in the mucous membrane of the lips and cheek.

In some cases, and before the disease is constant and the attacks frequent, and especially in stump and other traumatic neuralgias, the attacks are nearly all traceable to storms; but in others the chronal relations of such pain seem to be due to physiological laws which are as yet wrapped in complete mystery.

Sciatic neuralgias are more prone than others to be due to inflammatory states, and the tendency of these to be worse at night may well be related to the general

physiological law which gives rise to a normal elevation of temperature at night, and to a similar rise in the heat curve in fevers and in all states which give rise to febrile conditions. This is, however, but a more or less happy guess in regard to a problem most difficult of solution.

FIG. 2.

Shows the areas of complete and partial anæsthesia in the gums. The mucous membranes behind the teeth showed normal sensation. Section of inferior dental nerve at A. These diagrams were made twenty-seven hours after the neurectomy.

Dr. Morris Lewis examined the area of sensory disturbance before and after operation. Save for the slight hyperæsthesia, the neuralgia caused no change of moment, nor is it common to observe in these cases dysæsthesia. Dr. Lewis's diagrams represent the loss of pain sense within and without the mouth after the section by a dark space, and of loss of touch by a lighter one. These areas are somewhat smaller now than immediately after the neurectomy—a fact which I have often observed, and have elsewhere endeavored to explain.

It is to be observed that these sections are the only trustworthy means of obtaining a true surface map of the areas of nerve distribution; but, since surgeons are usually indifferent as to accurate study of such cases, we are still far from having profited as we might have done by neurectomy.

Our patient remains well at this date; but I should not be surprised were she to return to us with a reconstructed nerve and a renewal of the pain.

Two days ago, February 26, 1882, the patient again appeared at my clinic. She is entirely free from pain, and the area of insensibility is lessening. I was struck and interested to see that the chin muscles of the face on the left side were constantly quivering, and that they exhibited the electric reactions of muscles cut off from the centres. I was a little surprised at this, until our assistant physician to the hospital pointed out to me that the incision made to reach the nerve had been vertical, and that it had thus cut the lower branch of the seventh nerve, the filament which supplies the muscles of the chin.

ORIGINAL ARTICLES.

PREVENTIVE MANAGEMENT OF SMALL-POX.

BY WILLIAM H. FORD, M.D.,
OF PHILADELPHIA.

As there is no contagious disease whose prevention is so completely within human control as small-pox, it does at first sight seem strange that it should continue to commit its ravages among civilized people. Theoretically, nothing appears easier than its complete mastery and final utter eradication; but practically, the difficulties in the way of its suppression and radical extinction seem to be almost insurmountable. This results from the want of unanimity of sentiment with regard to the protective power of vaccination, from the absence of a general law requiring the vaccination of all persons, and its periodical repetition, and the lack of thorough and rigid application of other supplemental measures necessary to restrict the disease whenever it appears.

Universal vaccination is the main reliance in dealing with this dreaded plague; in fact, if this could be secured and maintained, there need be little or no recourse to other means of prevention. But as so desirable a result is not yet attainable, resort must be had to other measures which form an important and indispensable part of the preventive management of all contagious diseases.

Whenever a case of small-pox occurs, the chief and constant aim should be to prevent the communication of the disease to other persons. This is sought to be accomplished by prompt *notification* of the fact of the existence of the disease, by the *isolation* of the sick, by the use of *disinfectants*, and by the application of such *other measures* as tend to restrict the disease within the limits of its origin, to which allusion will hereafter be made.

Every case of small-pox should be promptly reported to the sanitary authorities, so soon as its nature is definitely determined. This duty is usually imposed upon the physician in attendance, or, when no physician is employed, upon the householder or responsible head of the family or institution where the case occurs. The law should fix the responsibility upon some one with such particularity that there can be no chance for evasion, and its violation should be made punishable by a heavy fine. The object of this notice is to afford the proper authorities the earliest opportunity for inquiring into all the circumstances connected with the origin of the disease, and the management of the patient and the premises, and for obtaining information on the questions of vaccination, attendance of children at school, and the relations of the case to the surrounding neighborhood, so that prompt and efficient measures can be instituted for restricting and preventing the spread of the disease.

It is absolutely indispensable, in the interests of the public health, that every case of small-pox should, from its very commencement, be completely isolated, either at home, or, when this is not practicable, in a hospital or some place specially prepared for the purpose. It is for the sanitary authorities to determine this question, and in exercising this function, every possible means of persuasion should be used to gain consent before the strong arm of the law is invoked, and the greatest care and caution should be observed in making the transfer in such a manner that the patient shall be exposed to the least possible risk to his health.

In the habitations of the poor, where there is always scarcity of space and a crowded condition

of the inmates; in dwellings where there is no place adapted for secluding the patient; in boarding-houses, hotels, public institutions, and places of general resort, such as dwellings connected with stores; or where the patient cannot be properly attended at home, either with regard to himself or the family, or both—there is unquestionably no doubt as to the propriety and duty of the prompt removal of the sick to a rendezvous or hospital specially prepared for such cases.

The isolation of the sick person implies his removal to a room most completely separated from every other part of the house—a veritable domestic quarantine. It should be well lighted, and well ventilated, and should have a fire-place, if possible, in which a fire should be kept constantly burning. All extraneous articles of furniture, carpets, and clothing should first be removed. The attendants should be chosen from among those who have had the disease, or who are protected by recent vaccination. No one should be permitted to have access to the apartment except those whose services are absolutely essential, and every precaution should be used with regard to cleanliness, disinfection of excreta, clothing, and everything in use in the room, so that there may be the least possible risk of spreading the infection. A sheet moistened with a strong solution of carbolic acid and suspended across the doorway, or in the passageway leading to it, is necessary to complete the isolation of the patient.

It is no longer considered admissible to treat cases of small-pox in general hospitals or public institutions, except in a separate pavilion isolated from the other buildings and managed under strict quarantine regulations; and even then this plan is objectionable, or account of the danger of multiplying the foci of contagion. Every town and city ought to be provided with a special place, either temporary or permanent, for the treatment of this disease in the event of its outbreak.

A law prohibiting the use of any kind of public conveyance whatsoever by a person affected with small-pox should be rigidly enforced, and its infringement should be made punishable by a heavy fine. In the event of such misuse of public vehicles, provision should be made for their speedy and thorough disinfection. Such a law necessitates the holding in readiness of special conveyances, or ambulances, for the transport of all persons affected with contagious diseases, and their use should be regulated by the health laws.

It is needless to say that every child, immediately upon the appearance of the first symptoms of small-pox, should be withdrawn from school, and its readmission should not be permitted without a properly attested certificate that it has entirely recovered, and that there is no longer any risk of its communicating the disease to others. Should there be other children in the family, they also should be required to leave school, though perfectly well, and should not be readmitted until provided with a similar certificate from a qualified sanitary officer stating clearly that the house is no longer infected, and that the danger of conveying the infection has ceased to exist. Only in very exceptional cases is it necessary to disband a school on account of small-pox having been discovered in some one or more of the pupils, since by properly performed vaccination, which should be an indispensible condition and prerequisite of admission to all schools, very general protection can be secured.

The inmates of an infected house should, so far as is practicable, cease to associate with the public, and their attendance at church, public entertainments, and assemblages of any kind, should be strictly interdicted. It would be advisable, if at all practicable, to have the well remove from the house, provided it is done early, and before there is any danger of thus communicating the disease.

The public ought to be apprised of the special locality where small-pox exists, lest they unknowingly expose themselves to the risk of contracting the sickness. How to accomplish this object without creating unnecessary public alarm, is a problem not so easily solved. It has been the custom in some places to placard the infected house with a conspicuous notice of the fact, but this plan has excited considerable opposition. The decision of the question might be left to every city or town to determine by its own experience. To depend upon the inmates of the house to warn all those who approach it, is trusting too much to the weak and selfish part of human nature. To have recourse to sanitary espionage, would be attended with the best results, if practicable, and not too expensive a procedure. It must be admitted, on the other hand, that the more rigid, harsh, and embarrassing the special requirements, the stronger the temptation and inducement for concealment of the disease. Better, perhaps, would be the plan of keeping the premises under general sanitary supervision, by occasional visits of officers qualified to advise and direct the observance of all prudential measures, and clothed with authority to institute more arbitrary and restrictive regulations as a penalty for non-compliance.

No public funeral should ever be permitted in these cases, and public notice of the cause of death should always be required.

No obligation to the patient or his friends is required of the physician to keep the nature of the disease a secret; on the contrary, by so doing he bemeans his profession, and dishonors himself in that he wrongs the public by pandering to the selfish interests of the few.

After death, the interment of the body, without an assemblage, as speedily as is possible consistent with propriety, should be the invariable rule; and once buried, the body should not be permitted to be disinterred, except after a lapse of time sufficient to preclude any possibility of infection therefrom; and even then this act should never be performed except under authorization and supervision of the local sanitary authority.

Another and most important means of restricting the spread of small-pox is disinfection, which consists in the destruction of the germs of the disease. The early, free, and constant use of disinfectants is a necessary part of the prophylactic treatment of every case of this disorder. In a certain sense, fresh air and sunlight may be considered disinfect-

ants; hence, there should be the freest ventilation of the room and house consistent with the safety of the patient. A fire upon the hearth contributes much to the active circulation of the air of the room. There should be the most scrupulous cleanliness with regard to the patient, attendants, bedding, and everything about the apartment. Everything from and about the patient should be promptly and thoroughly disinfected throughout the progress of the disease, and after its termination. This can be accomplished by burning, by thorough boiling, by exposure for a considerable length of time to dry heat of a temperature of 240° to 250° Fahr., and by the use of volatile and liquid chemical agents. At a temperature of 250° Fahr. some articles of clothing are apt to be scorched. A lower degree of temperature will probably answer the purpose of purification, if the articles are exposed to it for several hours, or for a sufficient length of time to insure the penetration of the heat to every part of the fabric; but it should never be lower than 220° Fahr. All the discharges from the patient should be received in a vessel containing some reliable disinfectant, such as a solution of two pounds of sulphate of iron, or of two fluidounces of chloride of zinc, or of four fluidounces of strong carbolic acid in a gallon of water, and thereafter immediately removed. When there are no sewers, the discharges from the patient, after thorough disinfection, should be deeply buried in the ground, far from the house and the source of water supply. Small articles, when soiled, should be burned, and the bed and body linen, when removed from the patient, steeped in the zinc or carbolic-acid solution above mentioned, and afterward boiled in water by themselves. The discharges from the nose and mouth may be conveniently received in a vessel charged with the chloride or carbolate of lime. To prevent the passage into the air of detached particles of infectious matter from the surface of the body of the patient, it is advisable to use inunctions of camphorated oil, or of sweet oil impregnated with carbolic acid, or of carbolated glycerine, to be applied daily to the whole surface of the body. It is very doubtful if the poisonous quality of the little particles floating in the air is at all affected by the amount of disinfection that it is safe to practise in the sick-room. There is, however, no objection to the use of chloride of lime or of the carbolic acid spray. But as aerial disinfection is practically of little value, the main dependence must be placed on free ventilation, cleanliness, and thorough disinfection, as already suggested. Food and drink that has been in the sick-room should not be used by other persons. The attendants should make free and constant use of disinfectants in cleaning their hands and articles in use by the patient, and nothing should be permitted to leave the room before first having been subjected to some form of disinfection. Every sink, water-closet, and privy-well in use during the sickness should be daily disinfected by the free application of some one of the above-named solutions, preferably that of the sulphate of iron, on account of its cheapness.

The clothing worn by attendants should be of such material as can be readily washed. Should it become necessary for an attendant to leave the house, a bath should first be taken, the hands, face, and hair being carefully cleansed with carbolic acid soap, and then only such clothing should be used as has not been exposed to infection. Subsequently, a free exposure in the open air is a wise precaution. Physicians cannot be too guarded in their attentions to themselves when attending a case of small-pox, as they are just as liable as other persons in attendance upon the sick to communicate the disease, and they should, therefore, as far as practicable, adopt the same precautions. A linen duster put on before entering the sick-room, and well buttoned up around the neck, will do much to protect the clothing from infection, and this should be hung up in the open air, after use, until the subsequent visit. The washing of the hands in carbolated water before leaving the house should not be neglected, as also the practice of exposure for a considerable time in the open air immediately after each visit. Before associating with other persons it would be well to first return home and remove all outer clothing, which should be hung up in the air for several hours. The thorough washing of the hands, face, and hair is also advisable.

The isolation of the patient should be continued for at least three weeks, or until all the scabs are removed and the skin is entirely smooth; and he should not even then mingle with other persons until after having taken a number of baths with the use of carbolic acid soap, and put on clothing that has not been exposed to infection.

After death or the removal of the patient, all articles of no value should be immediately burned, and everything in the room should at once be treated with a view to the complete destruction of the germs of the disease. This is to be accomplished by the use of the zinc or carbolic-acid solution above mentioned for steeping clothing,[1] washing floors, walls, and furniture. Wall-paper should be removed by moistening with the carbolic-acid solution. Heavy clothing, beds, bedding, and other articles which cannot be washed without injury, should be spread out in the room so as to be freely exposed to the influence of fumigation. Then, after closing all the doors and other openings as tightly as possible, the room and its contents should be fumigated by burning sulphur in an iron dish, set in a vessel containing a little water, and kept closed for about twenty-four hours. At the end of this time, the room should be well aired for several days by throwing open the windows, and then the ceiling should be whitewashed, and the walls repapered or whitewashed. This work, to be effectual, should be supervised by a competent officer of the Board of Health. For the purpose of fumigation it has been estimated that 2 pounds of sulphur will be required for every 1000 cubic feet of air-space.

The manner of treating infected conveyances and railway carriages is similar to that advised for infected rooms. They should be fumigated with sulphur, the wood-work washed with solutions of zinc

[1] For this purpose the National Board of Health recommends a solution made by dissolving four ounces of sulphate of zinc and two ounces of common salt in a gallon of water.

or carbolic acid, the cushions and stuffed furniture baked, and then beaten and exposed for a considerable time in the open air.

Often it happens that there are no facilities for carrying out many of these requirements, and in such cases the aid of the local authorities is of the utmost value. Some suitable place should be provided for disinfecting, at a nominal cost, all portable articles, particularly such as cannot be conveniently or satisfactorily cleansed and disinfected at home, such as stuffed furniture, beds and bedding, woollen clothing, and the like. Such articles could then be removed, with due precaution, in a wagon specially prepared for the purpose; those of no value being burned in a furnace, and the remainder, after being cleansed and thoroughly disinfected by steam, dry heat, or by chemical agents, according to circumstances, returned to the owners. This plan will prevent serious embarrassment, and will ensure a more complete purification than can be expected under ordinary circumstances, and its general observance will unquestionably do much towards the preservation of the public health. The city of Philadelphia has such a disinfecting service, and its benefits have been clearly proved by an experience of several years.

When a person dies of small-pox, the body should be washed with a solution of carbolic acid or of chloride of zinc, of double the strength of that indicated above, and enveloped in a sheet saturated with the same solution, and placed in the coffin as soon as possible. A metallic coffin, hermetically sealed, is preferable to all others; especially is this the case when the corpse has to be transported to a considerable distance. It need not be added that no public funeral should be permitted, and that burial should take place with the least possible delay.

TREATMENT OF SMALL-POX.

BY W. M. WELCH, M.D.,
PHYSICIAN TO THE MUNICIPAL (SMALL-POX) HOSPITAL, PHILADELPHIA.

IN discussing the treatment of small-pox, it will be found convenient to divide the disease into six stages, as follows: *1. The Stage of Incubation; 2. The Initial Stage; 3. The Eruptive Stage; 4. The Stage of Suppuration; 5. The Stage of Retrogression, or Stadium Exsiccationis; 6. Convalescence.*

1. The Stage of Incubation.—When the date of infection can be clearly determined, this is found to be a stage not very variable as to time. In most cases sickening occurs on the eleventh or twelfth day, and the eruption appears on the thirteenth or fourteenth day after exposure. During this interval very much can be done to prevent or modify the disease. For this purpose drugs, however, are useless; likewise, no dependence can be placed upon diet or hygienic measures. But it is to vaccination we must look to accomplish either one or the other of the desired results.

My experience does not agree with that of Curschmann,[1] in that he has not been able to prevent variola, nor even render its course milder, by vaccination during the stage of incubation. On the contrary, I have in numerous instances been able to afford perfect protection against variola, and have many times seen the disease markedly modified by vaccination after undoubted infection. In order, however, that protection shall be complete, it is necessary that vaccination be not too long delayed after exposure to the contagion. If the vesicle has reached maturity—the areola being well-formed—and the infected person has not yet sickened, the chances then for perfect protection are very good. But if sickening occurs a little in advance of this stage of the vaccine vesicle, so that the areola and the small-pox eruption appear about the same time, we then have reasonable ground for hope that the disease may be modified. Contrary to the rule, I think I have seen vaccination, in some rare instances, exert a modifying influence over small-pox when the eruption has appeared before the vaccinia had reached the stage of the formation of the areola; so that vaccination should always be performed, even though considerable time has elapsed since exposure. Usually, however, it will be found if the vaccination has been done somewhat late, that the vaccine vesicle and the variola eruption will develop side by side, without the former exerting any modifying influence over the latter.

Some years ago, I published[1] a brief clinical history of fifty cases, in which primary vaccination was done on various days during the stage of incubation of small-pox, and as my subsequent observations bear out the same general facts then stated, I will submit a short analysis of those cases. Of the fifty cases, ten were perfectly protected, three very nearly so, eleven partially protected, and twenty-six unprotected. Of the eleven partially protected, only one died, and that one was an infant only a few days old, and of premature birth. Of the twenty-six unprotected, fifteen died. Among those partially protected, the average length of time which intervened between the performance of the vaccination and the appearance of the variola eruption was 8.9 days; among those in which there was no protection, it was 6.9 days.

I wish to call especial attention to the fact that the vaccinations in the above cases were all primary. When a person has once been vaccinated, and there is a partial return of susceptibility to small-pox, protection after infection can be more readily accomplished by revaccination than where the vaccination is primary. The reason of this is not difficult of explanation. It is simply because revaccination develops and runs its course more quickly than does unmodified vaccinia, and hence, protection is more speedily brought about.

In order either to confer immunity, or to give the best possible protection against small-pox by vaccination during the stage of incubation, it is of vital importance that the lymph used should be fresh and active. For performing vaccination under such circumstances, my experience leads me to prefer humanized lymph, and that, too, somewhat remotely

[1] Author of article on Small-pox and Vaccination, Cyclopædia of the Practice of Medicine, Zeimssen.

[1] Philadelphia Medical Times, Feb. 17, 1877.

removed from the cow. The fifty cases of which I have spoken came under observation during the epidemic of small-pox in 1871–72, and were all vaccinated with lymph of long humanization. During the present epidemic, I have in almost all primary vaccinations failed to confer immunity against the disease after infection by the use of animal lymph. This is not because vaccinia induced by animal lymph possesses less prophylactic power, but because the course of the process is slower—the areola usually being two or three days later in appearing. The lymph, therefore, which produces the most rapid development of the vesicle and areola is to be preferred in times of imminent danger, as during the incubation of small-pox.

When there is good reason to believe that so much time has elapsed since exposure that it would be impossible to confer protection to any degree by vaccination, inoculation, were it allowable, might, perhaps, be practised with advantage. I have had, however, no experience in the use of this measure, and, consequently, cannot recommend it from any personal knowledge of its value. Besides the legal objection to the operation, there is the difficulty of determining the precise time at which infection occurs, and without this knowledge it would be impossible to say of any case that it is too late to expect protection from vaccination. While it would be reasonable to suppose that vaccination performed one week after exposure to the variola contagion would fail to exert any prophylactic power against the disease, yet such does not always prove to be the case. Quite recently a mother and her four children were admitted to the Municipal Hospital, the mother having small-pox at the seventh day of the eruption; three of the children were unprotected by vaccination, and the other, a girl aged eight years, had been vaccinated in infancy. All four of the children were at once vaccinated. The girl previously vaccinated took well-marked vaccinoid, and enjoyed immunity against small-pox. The other three children took vaccinia; of these, one was perfectly protected, one had an exceedingly mild form of varioloid, and the other unfortunately suffered from unmodified small-pox, and died. I might add that these vaccinations were done with humanized lymph of long descent, which was kindly furnished me by my friend, Dr. S. N. Troth, the senior vaccine physician of this City, who has preserved, with great care, the old stock of virus in use in this country prior to the introduction of animal lymph, in the year 1870.

2. *The Initial Stage.*—This stage usually comprises a period of two or three days. After what has already been said, it would be needless to enter into any argument to show that vaccination is useless at this stage of small-pox. The hypodermic injection of vaccine lymph has been suggested, and its claims urged, particularly by Furley;[1] but that it is wholly devoid of prophylactic power, I have had ample opportunity to prove.

All attempts to cut short the disease prove unavailing. Bloodletting, formerly much employed, is now almost never used, even for the relief of symptoms. Large doses of quinia during the stage of invasion has been thought to exert a favorable influence over the course of the disease, but Curschmann's large experience shows that it possesses no such value. In short, we can do nothing more at this stage than treat special symptoms.

The popular idea of ages ago still prevails to some extent that it is necessary to keep the patient hot and sweating, and not unfrequently it is found quite difficult to overcome this prejudice. A room well ventilated and having a temperature of 65° to 70° Fahr. is best suited to the comfort of the patient. Febrifuge mixtures, such as liquor ammoniæ acetatis, liquor potassæ citratis, tinctura aconiti, etc., may be given in suitable doses and at stated intervals. If there is much irritability of the stomach, the effervescing citrate of potassa may be preferable. When the temperature is high, sponging with cool water is serviceable. Severe headache, attended with a flushed face, may be met by the application of cold water, iced compresses, or the ice-bag to the head. For the irritability of the stomach, swallowing of small pieces of ice will sometimes give relief; subnitrate of bismuth is also of service. The nervous symptoms, such as insomnia, delirium, and convulsions, may be relieved by chloral hydrate and bromide of potassium, given either separately or combined. For the convulsions of children, chloral is especially serviceable. To relieve the pain in the back, which is often intense, Dover's powder, when the stomach is retentive, may be given. Gentle cathartics may of course be administered whenever indicated.

I would strongly advise against the application of mustard to the back for the relief of pain, to the epigastrium for the relief of nausea and vomiting, or to any other locality for any purpose whatsoever, because of the increase of eruption which it is sure to invite to that particular locality. I have frequently seen the eruption rendered excessively confluent on certain parts of the body by the application of sinapisms during the initial stage, and that, too, without the eruption anywhere else being diminished. This result is not peculiar to the action of mustard, but may be produced by any irritant or injury, and is doubtless due to the increase of capillary circulation which is thus artificially or accidentally brought about.

During this stage, the best beverages are cold water and iced lemonade. The diet should be light and easy of digestion.

3. *The Eruptive Stage.*—By this stage is meant the period beginning with the first appearance of the characteristic eruption, and continuing until complete pustulation has occurred. The duration of this period in variola vera is usually about seven or eight days. The great desideratum at this stage of the disease is a remedy which will control or modify the eruption, since danger is greatly dependent upon the quantity of the eruption and the long and tedious course which it pursues. It was thought that the antiseptic or antizymotic class of remedies would meet this indication, but after a full and fair trial, I think, concerning their alleged

[1] Lancet, May 25, 1872.

efficacy, the verdict *not proven* must be pronounced against them.

During the epidemic of 1871–72, I subjected seven cases of unmodified small-pox to the use of sulpho-carbolate of soda; the dose administered was twenty grains every three or four hours. The result was so discouraging that I abandoned the drug, for not one of the number recovered. Of the seven cases, four began taking the sulpho-carbolate on the second day of the eruption; of these, one lived three days; one, five days; one, eight days, and the other fifteen days. Two began its use on the fourth day of the eruption; of these, one lived two days, and the other three days. One began its use on the fifth day of the eruption, and lived twenty-one days. It is true, these were all very severe cases—all of them confluent, and some malignant. But they certainly represent a class of cases requiring specific treatment, were any such treatment known.

But my experience with antiseptic drugs is not limited to sulpho-carbolate of soda. I have also used salicylic acid, salicylate of sodium, and carbolic acid, the latter both internally and externally, but with results no more encouraging than those which followed the use of sulpho-carbolate of soda. With xylol I have had no experience.

Having decided negatively the question of specifics, it only remains for us to treat this stage of the disease, as the previous one, by regulating the condition of the patient, and giving attention to special symptoms as they arise. The febrile symptoms, which usually remit to a considerable degree after the appearance of the eruption, may, when present, be met by the remedies previously indicated. It sometimes happens in a depressed condition of the system that the surface of the body is cool, particularly the extremities, and that the eruption is slow in appearing. In such cases, the application of heat to the extremities, and the administration of hot stimulating drinks—hot toddy, for instance—may be of service. For the convulsions which frequently occur in children at the early part of this stage, a warm bath and hydrate of chloral, particularly the latter, given either by the mouth or rectum, have been found especially serviceable. Bromide of potassium may also be used. For the sore throat which now commonly appears, because of the eruption attacking the mucous membrane of the mouth and fauces, mouth washes and gargles, containing either chlorate of potassa, biborate of soda, glycerole of tannin, etc., may be used. Small pieces of ice allowed to dissolve in the mouth, and acidulated drinks, are often very gratifying to the patient.

During this stage persistent insomnia and violent delirium often occur, and for their relief large doses of chloral and bromide of potassium are sometimes required. In administering chloral, it is well to remember that it is very irritating to the throat, and, therefore, requires to be largely diluted; or it may be given by the rectum, if thought preferable. When this condition of the patient is attended by a flushed face and bounding pulse, a brisk cathartic may be of service. Tartar emetic and sulphate of morphia combined in doses of one-eighth to one-half grain each, will sometimes produce sleep and quiet the delirium.

Not unfrequently the patient in his delirium becomes so violent, and sometimes manifests a suicidal tendency so strongly marked, that it is found necessary, both for the safety of the patient and the protection of the nurse, to make use of some artificial means of restraint. I have known strong and muscular patients in this state of mind to knock down the nurse, jump out of the window, and make their escape. I have also known suicide to have been committed while the attention of the nurse was directed to another patient. In order, therefore, to guard against such accidents, we are in the habit of using in the Municipal Hospital for this class of patients, a wide band made of stout webbing or canvas, loosely placed over the chest and fastened to each side of the bed. Smaller bands made of the same material and lined with chamois skin are buckled on the wrists and ankles and also made fast to the bed, allowing, however, a little motion of the limbs, so that the patient shall not be subjected to painful restraint. By this appliance we are able to confine the patient to bed securely, without doing him any personal injury.

With the view of preventing or relieving the excessive burning and itching, particularly of the face, forearms, and hands, some ointment, such as cold cream or cosmoline, may be used. My preference is olive oil and lime-water in equal parts. This mixture may be perfumed with cologne water if thought necessary, and applied from time to time with a large camel's-hair brush. Cloths wet with cool water and spread over the face and arms sometimes afford relief. The development of the eruption within the hard skin of the palms of the hands, tips of the fingers, and soles of the feet, not unfrequently give rise to excruciating pain. For this distressing symptom very great comfort may be found in the prolonged use of lukewarm hand- and foot-baths. Or the frequent application of flannel cloths wrung out in tolerably hot water is of great service.

Patients suffering from the hæmorrhagic type of small-pox usually die during this stage. I know of no treatment that possesses any power against this form of the disease; for in my large experience I have never seen a well-marked case recover. I have tried antiseptics, large doses of quinia, iron in different forms, and ergot, without seeing any appreciable good effects.

The most suitable diet at this stage of the disease is a liquid or soft diet. It should, however, be nutritious, as the patient has yet to pass through a severe ordeal in which his power of endurance will be severely tested. In varioloid the appetite during the eruptive stage is often good; such patients require but little treatment, and may be allowed almost perfect freedom in choice of diet.

4. *The Stage of Suppuration.*—The duration of this stage may be said to be from two to five days. It is at this period of the disease that the eruption reaches its greatest development; that the suppurative, irritative, or so-called secondary fever occurs; that the mucous membrane of the mouth, fauces,

and larynx, become most dangerously involved; that the vital powers of the patient are most severely tested, and his life placed in the greatest jeopardy. The indications, then, for treatment are to relieve the dangerous throat symptoms when they occur, to mitigate the fever, and to resist by every available means the tendency to death by exhaustion. For if life can be prolonged through this stage of disease, the chances for recovery then daily increase.

The throat symptoms are rarely entirely absent, even in varioloid; but in confluent variola the eruption upon the mucous membrane of the mouth and fauces is usually also confluent, and often diphtheritic. Mouth-washes and astringent gargles are, therefore, indicated. As such, a solution of chlorate of potassa, alum, or borax may be used. If there is fetor of the breath, carbolic acid may be added; or diluted chlorine-water may prove of service. Curschmann prefers a weak solution of liq. ferri sesquichlor.

To relieve the pain and difficulty of swallowing, small pieces of ice held in the mouth and allowed to dissolve slowly are often of great benefit. Iced lemonade and mucilaginous drinks, particularly flaxseed tea containing sugar and lemon juice, are usually very grateful to the palate. The ice-bag applied to the neck is often of very great service. On the contrary, some patients are benefited more by hot applications. Should œdema of the glottis occur, an emetic may be given if the patient is not too weak to bear its action, or we may resort to local scarification.

When the eruption in the fauces and larynx assumes the diphtheritic condition all the distressing symptoms peculiar to diphtheritic croup are developed; the local remedies to be made use of for this condition are, of course, quite similar to those recommended for the latter disease. In addition to some of the measures already suggested, steam, inhalations of hot water or of water and vinegar mixed, may be of service; likewise the vapor from slaking lime is sometimes useful. Lime-water in the form of spray has proved serviceable. Also spray-inhalations of lactic acid (grs. xx. to ℥i.) may be tried. When suffocation threatens, tracheotomy may be employed.

During the period of suppurative or irritative fever of confluent variola the temperature usually ranges from 102° to 106° Fahr. Any measure, therefore, capable of reducing the temperature will prove of great benefit to the patient. Quinia in large doses has been recommended, but I have not found it of very great service. Cool immersion baths have been tried and not found very satisfactory; besides the difficulty of getting the patient in and out of the baths, they do not afford much relief. Cold compresses and cool water squeezed from a sponge over portions of the body, are more easy of application and are sometimes serviceable. I have seen patients benefited in warm weather by being covered with a sheet wrung out in cool water and renewed from time to time, but such applications are usually not well borne in cold weather.

The suppuration which takes place at this stage of confluent variola from the innumerable pustules spread over almost all parts of the body is certainly very abundant. Watson says the quantity of pus thus produced amounts to quarts. This excessive drain upon the system and the extensive cutaneous irritation combine to exhaust the strength of the patient, and consequently a vigorously supporting plan of treatment is required. A plan of treatment aiming to supply nutriment equal to the loss sustained through the suppurative process, was presented as long ago as 1856 by Dr. Nebinger,[1] and very appropriately named by him "Compensative Nutritive Treatment." Dr. Nebinger writes:

"In carrying out this treatment, I have not found any diet so useful, so grateful to the patient, or any which gave as little inconvenience to swallow, when the mouth, fauces, and throat were studded with pustules, as a combination of eggs, milk, sugar, and ice, made in the proportion of one egg well beaten, half a pint of milk, sugar and ice in quantities suited to the taste and desire of the patient. When the necessity for stimuli has existed, as it does in all cases of the confluent variety of small-pox, I have added brandy, or, what I think better, Monongahela whiskey, because for purity it can be more safely relied on, and can be more readily obtained. The quantity of this diet which I direct the patient to use in confluent small-pox is half a pint, or a tumblerful, with a large tablespoonful, or half an ounce, of Monongahela whiskey added to it, every two hours or every hour and a half *during the day and night.* I have frequently had patients to take as many as twelve eggs, three quarts of good new milk, and eight ounces of whiskey daily for several consecutive days; and yet, with all this supporting and stimulating diet, this most excellent proteine or highly nitrogenized food, these poor fellows barely escaped sinking into the grave, some of them having had (notwithstanding they were so vigorously supported with food, and so actively stimulated) that peculiar feebleness and tremor which is always the unmistakable evidence of a breaking up of the vital forces—the threatenings of dissolution."

My treatment at this stage of the disease, so far as nutriment and stimulants are concerned, has been almost identical with that of Dr. Nebinger. I have never given, however, as many as twelve eggs to one patient in twenty-four hours. To an adult patient suffering from very abundant eruption, I direct that there shall be given every twenty-four hours from two to three quarts of milk, from one to two pints of beef-tea, from two to four eggs, and from six to twelve ounces of whiskey, the latter being given in the form of milk-punch. The eggs may be well beaten and drank with the milk (a little salt being added), or they may be given in the form of egg-nog. It is important that the nutriment should be given at short intervals, and by night as well as by day.

Tonics are also indicated. I am in the habit of using quinia in doses of two grains every three or four hours. Digitalis is often of great service to steady the heart's action. Cathartics should be avoided at this stage. Where there is constipation, a laxative may be given, or, what is preferable, an enema may be administered.

The local treatment of the skin does not require to be materially different from that already indi-

[1] Variola; its Nature and Treatment. (Read before the Philadelphia County Medical Society.)

cated for the third stage of the disease. When the odor is disagreeable, as it is very apt to be at the latter part of this stage and the beginning of the next, carbolic acid may be added to the mixture of olive oil and lime-water (x.–xx. gtts. ad ℥i.). When there is a strong dislike to carbolic acid some other disinfectant may be substituted. At the period of the disease just referred to, the odor is often horribly offensive. Very much can be done towards correcting this condition by spraying frequently the face and arms, and even the bedclothing, of the patient with a five-per-cent. solution of either carbolic acid or Labarraque's liquid. Bromo-chloralum and Platt's chlorides may, in suitable dilution, be used in the same way.

In order to disinfect the atmosphere of the room, fresh air is of first importance, though care must be taken to prevent a draft of air from blowing directly on the patient, especially during the decline of the eruption. Chloride of lime is commonly placed about the room by the family, and may be of some service. I am in the habit of suspending in the room a large cloth wrung out in a solution of carbolic acid (Calvert's No. 4), or liquor sodæ chlorinatæ, in the proportion of an ounce of either of these to a quart of water. Care should be taken not to overcharge the atmosphere of the room with the odors of the disinfectants, the object being simply to correct the bad odor and render the atmosphere more agreeable to the patient and attendants.

5. *The Stage of Retrogression or Stadium Exsiccationis.*—This stage is characterized by the drying of the eruption. It may be said to begin about the eleventh, twelfth, or thirteenth day, and it runs very gradually into the stage of convalescence. During the early part of this period of the disease, the treatment marked out for the previous stage should be continued. When the patient shows marked indications of improvement, the quantity of milk, eggs, and whiskey may be gradually diminished, and soft or solid food substituted. The tonic doses of quinia should be continued, and the muriated tincture of iron may also be given with advantage. Of course, the applications to the skin and the disinfectants should be continued as long as required.

When complications occur, it is usually at this stage of the disease that they make their appearance. The most common complication is corneal ulcer. When this is observed early, I have seen good results follow the use of the solid stick of nitrate of silver —it being brought to a fine point, and applied very delicately. Solution of atropia should then be instilled in the eye, and hot compresses applied. It often happens, however, that the ulcerative action cannot be arrested by any treatment, but marches rapidly on to complete destruction of the cornea, and iritis, and sometimes suppuration of the globe follow. Pneumonia or pleurisy occurs perhaps next in frequency. Their treatment should be conducted on general principles, except that bloodletting, general or local, is not warrantable.

6. *Convalescence.*—During convalescence, a general tonic treatment may be demanded. Very often, however, little or no medication is required, the patient having a good, even voracious appetite, and rapidly regains flesh and strength. But not unfrequently sequelæ appear at this stage and greatly protract convalescence. Of these, the most common are boils and multiple abscesses. Their treatment requires the application of hot fomentations until suppuration is established, and then the free use of the lancet. When these furuncular processes are numerous, and continue to be reproduced for a long time, I have seen good results follow the administration of Fowler's solution.

Erysipelas, also, not uncommonly occurs—more frequently, doubtless, in hospital than in private practice. The affection is usually amenable to the ordinary treatment: that is to say, thirty drops of muriated tincture of iron, repeated every three hours, and the external use of diluted lead-water, are very promptly followed by favorable results.

Night-sweats are sometimes complained of, and when they occur, may be successfully treated by aromatic sulphuric acid, atropia or belladonna. The latter is often especially serviceable.

When decrustation is slow in taking place, glycerine or cosmoline may be applied. Warm baths, frequently employed, very greatly assist the falling off of the crusts. After the removal of the scabs, we can do nothing to remedy the cicatrices; but sometimes warty nodules are left on the face, which may be benefited by painting them with tincture of iodine.

Patients who have recovered from small-pox should not be permitted to mingle with other persons until all the scabs have been removed, for these latter doubtless contain the contagion of the disease.

The Prevention of Pitting.—The question how to prevent pitting in small-pox has taxed the ingenuity of physicians of all ages. Various methods have been recommended—some, indeed, highly lauded—but I think the judgment of those who have had the greatest opportunities for observation will bear out the statement that the end aimed at is never attended with certainty. In order to accomplish this end it is necessary that the eruption should be checked in its course before it has reached the pustular stage; for the suppurative process is attended with destruction of derm tissue, and then cicatrization and cicatrices must inevitably follow.

All the methods most highly recommended have, in my hands, failed to produce any satisfactory results. I have never been able to make any decided impression on the eruption by the application of mercurial ointment. I have tried tincture of iodine locally in the papular stage of the eruption, and find that it not only fails to modify its course, but aggravates the inflammatory action of the skin. The evacuation and cauterization of the vesicles have not, in my experience, been followed by any very decided benefit; at any rate, the procedure is only practicable in mild cases, where there is the least danger of pitting. I cannot too strongly condemn the application of collodion or solution of gutta-percha, as they form an impermeable coating, prevent exhalation from the skin, and consequently greatly increase the suffering of the patient. I have about come to the conclusion that Gregory was not far wrong when he said, "There is no peculiar

method which can be devised for the prevention of pits and scars. The masks and ointments formerly in use for that purpose, and so highly vaunted, are, in reality, more hurtful than beneficial. The application of a little cold cream to the hardened scabs is all that can be recommended."

HOSPITAL NOTES.

PHILADELPHIA HOSPITAL.

(Service of J. William White, M.D.)

RUPTURE OF THE URETHRA FOLLOWED BY EXTENSIVE INFILTRATION OF URINE.

(Reported by C. J. Seltzer, M.D.)

Andrew O., æt. forty-one, married, a pedler, was admitted into the wards of the Philadelphia Hospital January 24, very much exhausted and in stupor. No reliable history could be obtained from him further than that he had been drunk for some time up to six days before admission, during which six days he was lying in the condition he presented when admitted, and that he had but little medical attendance during that time.

The following was his condition after entering the ward: Pulse 120 to 130, rapid and feeble, intermittent, and at times almost imperceptible at the wrist. Respiration irregular, labored, and between 30 and 40 per minute. The breath had a peculiar sweetish odor. Tongue was pointed, dry, and brown. Teeth and lips covered with sordes. Examination of what the patient supposed to be hæmorrhoids showed a large slough in the right gluteal region, surrounded by numerous small abscesses and sinuses.

The perineum was very much swollen and distended, but no distinct fluctuation could be obtained. The inflammation and swelling extended from the anus to the scrotum, the latter but slightly involved. There was also a large ischio-rectal abscess. Pressure upon the perineum caused the urine to flow from a sinus, extending towards the rectum, but not communicating with any cavity, as far as could be ascertained.

A small flexible rubber catheter was introduced into the urethra to the depth of eight inches, meeting with no resistance. The bloody and purulent character of the urine, and the increased flow when pressure was made over the perineum, indicated that the catheter entered a false passage and not the bladder. The urine contained a large quantity of pus. In withdrawing the catheter, the urine continued to flow from it until about five inches of the catheter remained, when it ceased abruptly. Sensation had almost entirely disappeared from the affected parts.

After the administration of whiskey and digitalis at short intervals, the patient revived to some extent. Pulse became less frequent and stronger; respiration better. After careful etherization the patient was placed upon the operating-table in the lithotomy position, and perineal section performed by Dr. White. A metallic catheter having been introduced, a linear and deep incision was made into the centre of the perineum. A cavity filled with urine and pus was laid open, and its contents evacuated. The end of the catheter was found in this cavity, having passed out from the urethra on the right side between the spongy and cavernous bodies, and thence into the cavity between the bladder and rectum.

A catheter of small size was now passed into the bladder, and a large quantity of urine drawn off. The sloughing tissues were removed, sinuses and abscesses laid open, and a charcoal poultice applied. Stimulants were freely administered, and external heat applied. The catheter was retained, and the urine drawn off at intervals during the day.

The tissues from the scrotum to the rectum were discolored and gangrenous. Whether the abscesses existed before he went under treatment, or before infiltration of urine took place, it is impossible to say, since no history of his condition previous to admission could be obtained; but, as will be seen from the autopsy, it is probable that a false passage had been made during attempts at catheterization previous to his admission.

After the operation, and when the effects of the ether had passed off, the patient was able to answer a few questions about his condition as to pain or discomfort, and sensation was also re-established to some extent. Eight or ten hours after the operation coma returned and became profound, and remained so until death, which took place thirty hours after.

The following was the *post-mortem* condition: Upon laying open the abdomen, the surface of the intestines and wall of abdomen were found to be normal, as was also the liver; but when an attempt was made to remove the intestines, they were found bound down upon the right side by old, firm, and strong adhesions. Numerous cavities filled with pus existed throughout this region, and the surrounding tissues were matted and saturated with purulent fluid. The principal cavity was external to the kidney, between it and the peritoneum. This tract extended from the right kidney into the pelvis, in the course of and surrounding the ureter of that side. The pelvic cavity was filled with purulent fluid. The kidneys themselves were very much enlarged and white, and showed, microscopically, evidence of extensive parenchymatous nephritis. The left contained a little pus. Both ureters were dilated and enlarged, with thickened coats. The dilatation was greatest about the centre; the right more so than the left. The pelvic organs were also bound together by old adhesions. Neither of the cavities found in the abdomen had distinct or well-defined walls.

The bladder was very much hypertrophied and dilated, the mucous membrane lining it thickened and forming ridges which ran in various directions. The orifices of the ureters were enlarged and opened straight into the bladder.

An abscess seated in the middle lobe of the prostate communicated with similar ones in the lateral lobes. Pus also escaped from the follicles in the membranous urethra. Collections of pus were found in the tissues beneath the pubes and in front of the triangular ligament, also in the bulb.

By laying open the urethra its entire length two strictures were found; one, two and a half inches from the meatus, and the other five inches. Numerous lacerations in the first stricture showed that it had been forcibly dilated. This stricture was a membranous contraction, without any induration whatever. The second stricture was of an entirely different character, being indurated and hard to the touch, seven-eighths of an inch in depth, and situated in the spongy urethra, extending almost to the beginning of the membranous portion. Several fibrous bands crossed in the course of the stricture. Between this stricture and the bladder the urethra was unbroken, though slightly dilated.

The rupture took place at the beginning of the second stricture, on the right side, and entered the perineum between the corpus spongiosum and corpus cavernosum, five inches from the meatus urinarius. The principal cavity in the perineum extended from the seat of rupture, posteriorly, almost to the rectum. The bulb was dissected out by the infiltration, so that when the cavity was laid open it was entirely exposed to view. The cavity was almost completely upon the right side—the side upon which the rupture occurred.

MEDICAL PROGRESS.

TRICHINOSIS.—In a recent instructive lecture on the subject of trichinosis M. GERMAIN SÉE distinguished four clinical types under which the symptoms may manifest themselves. The first is the gastro-intestinal form, in which the affected individuals are seized with grave digestive troubles without apparent cause, epigastric discomfort and sense of distention, nausea, and vomiting. The times of the vomiting vary; sometimes they occur on the day on which the trichinous food was taken, sometimes they are delayed for four or five days. The vomiting is usually accompanied with diarrhœa, sometimes choleriform in character. Such symptoms, if slight, may be readily mistaken for a simple indigestion. If the nature of the disease is, however, suspected, the diagnosis may readily be made by the discovery of the entozoa in the stools. When the diarrhœa is excessive the symptoms may resemble those of cholera, but two distinctive characteristics are the excessive perspirations and considerable muscular prostration, which may even precede the onset of the diarrhœa. In the second, or rheumatoid form, muscular pains are the dominant symptom; muscular exertion is painful, and causes fatigue. Towards the eighth day the muscles become swollen, hard, and tender, and the flexors are always more affected than the extensors, and from the swelling of the muscles, shortening, and even a flexor contracture, may result. Painful trismus or difficult deglutition may be the effect of the presence of the trichinæ in the muscles of the jaw and pharynx, and the affection of the laryngeal muscles may change the voice, and that of the intercostals and diaphragm may cause a painful dyspnœa. With these are spontaneous pains, often severe, irregular in distribution, not corresponding to the course of the nerves, and constantly mistaken for rheumatism. In this form, also, there are usually initial gastro-intestinal troubles, which (as well as the prostration) should always arouse suspicion. The third and most characteristic is the œdematous form. The patients make their appearance with swollen faces, particularly the eyelids, and they complain of extreme prostration. The swelling may be bilateral or unilateral, and in the latter case is pathognomonic. This œdema, with normal heart and urine, with muscular prostration and initial gastro-intestinal troubles, should leave the diagnosis in little doubt. The last is the typhoid form, between which and enteric fever there are several analogies. There is continuous fever, considerable prostration, some dyspnœa, and much muscular pain. Three distinctive symptoms, however, are the profuse sweating, the œdema of the face, which is present in nine out of ten cases of trichinosis, and the brief duration of the pyrexia, which ceases although the other symptoms persist. The last is the gravest form, and death may occur in the second or third week with delirium or stupor, and the general aspect of a severe case of typhoid disease.—*Lancet*, Feb. 11, 1882.

AN ANTISEPTIC FOR INSTRUMENTS.—Dr. MATHEWS DUNCAN states that salicylic cream, composed of one part of the acid to four or five of glycerine or vaseline, is a valuable means of keeping sponges, tents, instruments, etc., aseptic in the vagina. It was first suggested by Dr. Ogsten, of Aberdeen.

TREATMENT OF RINGWORM.—In order to prevent the spreading of ringworm by contagion, and when occurring in children to prevent their losing their school hours by being kept at home, Dr. THIN recommends the covering of the head with an ointment. He reports a case in which for two months the patches were kept covered with fat melted with a sufficient quantity of white wax to give the mixture consistence at the temperature of the skin. During these two months the patches of ringworm remained absolutely stationary. The spread of the disease was at once arrested, although the spores present in the diseased hair-follicles still retained their vitality. The boy had a brother and two sisters, under the age of puberty, with whom he had constant intercourse, and no precautions were taken beyond his wearing a cotton skull-cap; but none of the others took the disease then or afterwards, when stimulating ointments were applied in order to effect a cure. —*Lancet*, Feb. 11, 1882.

CONGENITAL SACRAL FISTULÆ.—An interesting discussion occurred at a recent meeting of the Paris Société de Chirurgie on a point in teratology, which has attracted but little attention, viz., the curious congenital fistulæ which are met with in the neighborhood of the sacrum. M. TERILLON described three cases of this condition, and noted the occurrence, in connection with these fistulæ, of inflammation due to the accumulation of sebaceous material, just as inflammation from the same cause occurs at the umbilicus. In one case the fistula passed up to the bone of the sacrum, which was, however, not exposed. The matter which escaped from the opening contained much fat and squamous epithelium. After excision the walls were found to have a structure similar to that of the skin. M. FÉRÉ has examined a large number of children with reference to this question, and found in several a small depression in the corresponding position, and in two there was an actual cul-de-sac, about half a centimetre deep. Two hypotheses were put forward respecting the origin of these cavities. One regards them as an incomplete spina bifida, but against this is the fact of the integrity of the vertebral arches. According to the other theory, these fistulæ are relics of the "posterior umbilicus;" but authorities are by no means agreed as to the situation of this, some placing it in the middle of the vertebral column, others towards its lower part. M. DESPRÈS mentioned an instance of congenital tumor containing epithelial cells situated in this region. The frequency with which a caudal appendage or a tuft of hair was found in the neighborhood of these fistulæ was insisted on by M. GUÉNIOT. Similar cases were mentioned by CHAUVEL and POZZI, but no additional evidence was adduced as to their nature.—*Lancet*, Feb. 11, 1882.

INFLAMMATORY ENLARGEMENT OF BONES.—Mr. C. J. SYMONDS from a paper on this subject concludes: 1. That ostitis, even when central, is only attended with enlargement when the periosteum is involved. 2. That in all cases of primary synovial disease of joints, or of caries of articular surfaces, with secondary synovial disease, there is no enlargement of the bone. 3. That the enlargement of joint-ends in these cases is only apparent, and is explained by the unnatural prominence of the femoral condyles, owing to wasting of the thigh and to the thickening of the ligaments and synovial membrane. 4. That all inflammatory increase in the size of bones is due to periosteal formation, and that the uniformly cancellated appearance is due (*a*) to the widening from absorption of the spaces in the compact layer, whereby it becomes indistinguishable from the original cancellous tissue and the porous periosteal bone; and (*b*) to the remodelling of the compact layer when the ostitis has been superficial. 5. That the term "expansion" is misleading as applied to the results of the inflammatory processes in bone, since the widening of the spaces is an absorptive one.—*Lancet*, Feb. 11, 1882.

CHLOROFORM MORTALITY.—The number of deaths at present occurring from the administration of chloro-

form is so startling, that it is arresting public not less than professional attention. On Wednesday week last one of these fatalities occurred at Malvern Wells, and is a fair specimen of many more. The patient, Charles Holmes, a man fifty-one years of age, consulted Mr. Haynes for dislocation of the shoulder. Mr. Haynes tried the usual modes of practice for reducing the dislocation without anæsthesia, but did not succeed, and, failing, determined to reduce under chloroform. He took every reasonable precaution before carrying out this intention. The examination of the heart gave no indication of disease, and there was no obvious reason why the narcotic should not be employed. It was also used with due care, but during the second degree of muscular excitement the patient became collapsed, and rapidly died. The *post mortem*, conducted by Mr. H. J. Brown, of Worcester, revealed "long-standing structural disease," fatty degenerative change, we presume, of all the vital organs; so that "the man might have died at any moment." The class of case here presented is typical. There is a large population of this kind, a population of men and women, but of men especially, who, without presenting, even to skilled observation, their precise state, are liable to die at any moment. They die from slight mental shocks; they die from comparatively slight physical shocks; they die under efforts to run or climb; they often die in attempting to catch the train against time; they die in the most ready manner under certain of the anæsthetics. It is probable they are in danger under any of the anæsthetics which are as yet known, but it is certain that they are in great danger under every one of the class that belongs to the chlorine family. The chlorine, which really has nothing to do with the production of the anæsthesia, for that depends on the organic radical with which it is in combination, is the cause of the danger. It acts as an irritant. It produces sudden contraction of arterial fibre, arterial shock, by which the course of blood through the pulmonary and systemic circuits is impeded, and the feeble heart, unable to meet the difficulty, is arrested in its action during the second degree of anæsthetic sleep. The practical lessons to be remembered on this very solemn subject are always deserving of mention. In the first place, there can be no doubt that when any suspicion exists that life is not at its best, and that the heart is feeble, ether should take the place of chloroform. Ether relaxes, and for a case of dislocation is singularly superior to chloroform. If the administration of ether is, for any reason, not practicable in the class of case to which we refer, then the chloroform administration should be preceded by a full dose of some agent that has the relaxing effect of ether, and that agent we have at hand in ethylic alcohol. From one to two ounces of pure alcohol—specific gravity 830—is a valuable preliminary, and should be given diluted in eight ounces of water from five to ten minutes before the inhalation of the narcotic is commenced. With these precautions, the dangers of anæsthesia may be greatly reduced; and they ought to be rigidly followed until the time comes when science shall give to us a new agent that, with all the facilities of chloroform, in respect of convenient and ready administration, shall combine the safety, with something more than safety, of anhydrous ether.—*Lancet*, Feb. 11, 1882.

Sore Nipples.—Dr. Favre (*Petersburg. Med. Woch.*, Jan. 28), distinguishes two kinds of this lesion—fissures and erosions—and, believing that the latter are much induced by the modern tight-fitting dresses and the pressure of the corset, warns pregnant women against this mode of procedure. As a means of treatment he recommends the sprinkling the sores with bismuth, or employing this as an ointment, in the proportion of two drachms to half an ounce of vaseline. In some cases, twenty-four hours' application of this means has removed all suffering, and allowed suckling to be resumed.—*Med. Times and Gaz.*, Feb. 11, 1882.

Hydrophobia Treated with Pilocarpine.—To prevent the multiplied trials of useless drugs, it is well to note the unsuccessful use of remedies in hydrophobia. A case in Paris has been reported in *La France Médicale*, in which pilocarpine was employed without apparently retarding for a moment the fatal result. The patient was a man, aged thirty-eight, who was bitten on the 23d of February by a rabid dog. The wound, which was situated on the hand, was cauterized by carbolic acid, and cicatrized slowly. For two months no symptoms appeared. Then a dull pain seemed to start from the wound and to ascend the arm to the shoulder and trunk. Two days later the first paroxysms occurred, and the disease ran a rapid course, with its customary symptoms. Six injections of pilocarpine were given, two centigrammes in each, and caused abundant salivation and less copious diaphoresis. When the effect of each was over, the patient experienced a notable relief to his sufferings; but the course of the malady appeared to be altogether uninfluenced. The salivation which was produced by the later injections was attended by terrible paroxysms of suffocation, followed, however, by distinct relief. The loss of liquid occasioned by the treatment increased the thirst; but deglutition was impossible. A tube was therefore passed down the œsophagus, and as much liquid as possible introduced into the stomach. The operation was well borne and, on repetition, the patient himself introduced the tube. Forty-eight hours after the commencement of the treatment the patient died suddenly. He was sitting on his bed, talking, when his head sank forward on his chest, he gave one or two inspirations, and was dead. Sudden death from cardiac failure is too common in hydrophobia for the result to be ascribed with certainty to the pilocarpine, but it should teach caution in the use of so depressing an agent in the disease.—*Lancet*, Jan. 21, 1882.

Scrofula and Tuberculosis.—M. Grancher recently made to the Société Médicale des Hôpitaux of Paris an interesting communication on the above subject. The following are his general conclusions: 1. Tubercle is a fibro-caseous neoplasm, the development of which takes place in successive stages, during a longer or shorter period; this complete evolution may be accomplished in a few months, or it may last throughout the whole of life. It may, however, be arrested during the earlier stages, and never get beyond them. 2. Pathological anatomy and experimental pathology are to-day agreed to include under the term tuberculosis the greater number of affections called scrofulous, as *local* tuberculoses. 3. Lupus and superficial inflammations of skin and mucous membranes, the last resort of those who persist in regarding scrofula and tuberculosis as distinct, will probably be included in the same order in due process of time. 4. The necessities of practical medicine, which, after all, must first be reckoned with, do not permit all tubercular affections to be confounded together; on this account it is convenient to retain the word "scrofula" for those tubercular affections which are very slight and generally curable.—*Med. Times and Gaz.*, Feb. 11, 1882.

Iodide of Lithium.—Prof. Deisse recommends the administration of iodide of lithium in the form of pills, in cases of syphilis, where iodine is indicated but where the idiosyncrasy of the patient prevents the use of iodide of potassium or the other ordinary iodine preparations. His formula is as follows: ℞. Iodide of

lithium gr. 23½, powder and extract of quassia enough to make 20 pills. One pill to be taken in the morning and evening. Iodide of lithium is very hygroscopic and must, therefore, be kept in closed boxes.—*Wien. Med. Zeitung.*, Jan. 21, 1882.

TREATMENT OF SEVERE EPISTAXIS.—Dr. THÉODOR ROTH recommends, in cases of epistaxis sufficiently severe and prolonged to endanger life, the use of acetate of lead associated with opium, administered in the following form:

Sub. Acetate of Lead,	. .	0.12 centigramme.
Opium,	. . . . .	0.01 "

A powder to be taken every two hours.

The author adds that three grammes of acetate of lead, and 0.40 centigrammes of opium, should be taken in three days in order to obtain a complete cure.—*Rev. Mens. de Laryngologie, D' Otol. et de Rhin.*, Jan. 1, 1882.

TOXIC ACTION OF SALIVA.—M. GRIFFINI has undertaken to repeat the experiments of MM. Pasteur and Vulpian on the toxic action of saliva injected under the skin, and has communicated an article on the subject to the *Archivio per le Scienze Mediche*, t. v. He obtained both pure parotidean and mixed saliva, and injected both fluids beneath the skin in rabbits. He believes that pure parotidean saliva is perfectly inoffensive, that ordinary mixed saliva filtered through porous plates, so as completely to prevent the passage of microbia, does not produce any local gangrenous changes, but a general infection of the blood, resembling in all essential respects septicæmia. He has satisfied himself that it is the saliva, and not the microbia that it contains, which produces the septicæmic condition. Mixed unfiltered saliva contains much more toxic constituents, due probably to commencing putrefaction or to fermentation in the buccal cavity; hence, when this is subcutaneously injected, gangrenous complications occur with necrosis of the tissues and ordinary septic accidents due to the resorption of gangrenous products. M. Griffini considers that his experiments prove that the toxic action of saliva is due to a non-organized ferment.—*Lancet*, Feb. 18, 1882.

THE ETIOLOGY OF SCARLATINA.—Dr. EKLUND, of Stockholm, has for several years devoted much time to the study of the pathology and etiology of scarlatina, which is constantly present in the Swedish capital, and rarely absent from the barracks and other dwellings on the Isle of Skeppsholm. The results at which he has arrived cannot fail, if confirmed by other observers, to be of the highest practical importance as solving the connection, too frequently seen to be ignored or explained away, between bad drainage or other insanitary conditions and outbreaks of scarlatina, which otherwise must be admitted to have been produced spontaneously—*i. e.*, without actual infection. In the urine of persons suffering from scarlatina, he has constantly found a prodigious number of discoid corpuscles, oval or round, their diameter being less than $\frac{1}{1000}$ millimetre, or from a thirtieth to a tenth of that of a red blood-cell. They are colorless or yellowish-white, surrounded by a distinct cell-wall, and containing a well-defined nucleus of a deeper hue; sometimes one or more nucleoli may be seen. They exhibit rotatory or oscillatory movements, especially when a drop of water is added to the fluid. They multiply themselves, as he has frequently observed, by fission, first of the nucleolus, next of the nucleus, and finally of the entire cell. He cannot say whether they develop into a mycelium; at any rate, the presence of fine filaments seems to be exceptional. He has never seen them to adhere in moniliform chains nor massed as zooglœa. He considers them to be veritable *schizomycetes*, and proposes the name of *plax scindens*. But Dr. Eklund most positively asserts that he has found these identical organisms in vast numbers in the soil and ground water of the Isle of Skeppsholm; in the mud from the trenches dug for the water-mains; and among the greenish moulds of the walls of the old barracks, where scarlatina was most rife. Nay, more, he alleges cases of scarlatina occurring in children after drinking milk mixed with the ground water of the island, and one case which followed on immersion in one of these trenches, and the drying of the child's clothes in a small room. In still another case, scarlatina broke out in a block immediately on the exposure of the ground water by excavations around. Other observers have found micrococci in the animal fluids in scarlatina, but, even if they were shown to be invariably present in the disease, it would not prove that they were its cause. Still less can the connection of the extra-corporeal organisms with scarlatina be demonstrated by anything short of direct verification, by inoculation into a healthy body, carefully isolated from all other sources of infection. It is the absence of this last condition of scientific precision, which casts a doubt on all conclusions drawn from accidental, or, as Mr. Simon would say, popular experiments.—*Med. Times and Gaz.*, Jan. 28, 1882.

THE NERVE-ELEMENT IN WHOOPING-COUGH.—Of late years the profession has bestowed very little, if any, serious scientific attention on some of the commonest of common maladies. Whooping-cough is conspicuously among the neglected ills to which, notwithstanding the forgetfulness of the multitude of earnest clinical investigators, flesh is still heir. Many years ago the nerve-element in this troublesome and too often evil-working, if not in itself dangerous, affection, engaged much consideration, and treatment was specially directed to its relief. It would be well if the investigation of this feature of the etiology of the affection could be resumed. The fact that pertussis belongs to the class of maladies which are communicable and "catching" does not take it out of the range of probability that the specific action of a morbific poison on the nerve centres may be the efficient cause of the disease. Although the occurrence of the affection happening rarely more than once in the life of any individual may seem to point more directly to the fertilizing of latent germs in the organism than to any special excitation of the nerve centres, we do not, as yet, know enough of the *modus operandi* of morbific influences—"germs," or poisons, as we call them—in the blood and the tissues to define the part which the nerve centres play in the production of morbid phenomena. In any case, such relief is frequently obtained even in the earliest stages of whooping-cough from mild periodic counter-irritation over the whole length of the spinal column by a mustard poultice, which merely reddens the skin without vesication, that it would be well worth while to study this method closely from the therapeutic as well as the clinical standpoint. It certainly does good; but how? In cases where the mustard poultice, applied for six or eight minutes—not longer—over the whole length of the spine immediately before putting the child to bed every night, for a week, or, in seriously spasmodic cases, a fortnight, does not procure a permanent amelioration of the cough, the effect of this remedy is enhanced by sponging the spine with iced water quickly each successive morning. In cases where the paroxysms of cough seem to be repeated and to continue from sheer exhaustion of the nerve centres, coffee, administered as a drink, will often stimulate the energy of the centres, so as to put an end to the malady. These are practical points which require theoretical explanation.—*Lancet*, Jan. 28, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, MARCH 11, 1882.

NEPHRECTOMY.

WE considered last week the subject of nephrotomy, but nephrectomy, or extirpation of the kidney, is so recent and so promising an operation, that it deserves a few words, especially as the first number of our weekly issue contained a notable case by Dr. T. Gaillard Thomas.

As America led in ovariotomy, so it has the honor of the first two cases of nephrectomy (though undesigned) by Wolcott, in 1861, and Peaslee, in 1868. But the first deliberate and intentional operation was done by Simon, in 1869. His work *Die Chirurgie der Nieren*, Martin's paper in Langenbeck's *Archiv.*, for 1879, Torres' Thesis, *Des Calculs des Reins*, Barker's two papers in the *Medico-Chirurgical Transactions*, for 1880 and 1881, Kroner's in the *Archiv. f. Gynäkol.*, vol. xvii., and several papers by Czerny and others in the *Transactions of the London International Congress of 1881*, with the reports of the various cases published from time to time in the *American Journal of the Medical Sciences*, are the best sources of information up to the present time. Czerny reports 74 cases, to which must be added one each by Thomas and Burgess, making 76 cases in all. Of these 10 are American and 66 foreign. How rapid has been the growth of the operation in favor, may be seen by the fact that up to 1875 Nepveu had collected only 14 cases, in 1880 Barker reported 28, and now we have 76. Czerny himself up to last August had operated 13 times with 7 successes.

One great fear had been that on the removal of one kidney the increased vascular pressure and extra work thrown upon the other, would induce disease, and especially albuminuria. Simon's careful preliminary experiments on dogs, confirmed by those of Torres, made this improbable, and the results of the now numerous operations in man have entirely dissipated this fear. The other kidney undergoes simply a compensatory hypertrophy. Moreover, no uræmia has followed, except in a few cases of absence or destruction of the other kidney, no hypertrophy of the heart, no shock from vaso-motor disturbance by a ligature so near the solar plexus and the aorta, in fact, no extraordinary effects whatever. The dangers are precisely those of ordinary surgical operations—no more, no less—and, in corroboration of the assertion of Torres, which we quoted last week, Thomas is undoubtedly right in saying, "that the operation is now one of the recognized and legitimate procedures of surgery."

It has been repeatedly performed on children, in one case at eleven months of age, and even, by Gilmore, successfully at the fifth month of pregnancy, without producing abortion.

It is not a little surprising to see how frequently a painful floating kidney has necessitated the operation, while neoplasms, fistulæ of the ureter, calculi, hydro- and pyo-nephrosis, and other similar conditions, at times, have led to it.

The question of the lumbar *vs.* the abdominal incision, is perhaps at present quite as important as that of diagnosis, and it is in the selection of suitable cases, and the appreciation of the conditions favorable to the one or the other method of operation, that immediate improvement of the operation lies. Floating kidneys and very large tumors, such as have been so frequently mistaken for ovarian or other tumors, can generally be removed most successfully by the anterior incision, and in this class most cystic, encephaloid, and other similar neoplasms, will be found. Moreover, the greater readiness of access to any neighboring diseased glands which ought to be removed, is an additional argument for this method. Czerny, however, in one case, reported by Braun, made a lateral incision, nine inches long, from the sacro lumbalis parallel to the border of the ribs, and was able to remove the tumor without wounding the peritoneum—a method which deserves future trial. On the other hand, if the perinephritic tissue be much thickened, and many adhesions have already been formed, the lumbar incision offers manifest advantages, both in access to the kidney and its vessels, and the operation is simplified by a simple enucleation of the organ from its capsule, leaving the inflammatory products behind, thus not interfering with the peritoneum. So, too, with smaller neoplasms, in which the glands are not yet probably involved, and in cases of pyo-nephrosis and calculus pyelitis, and of fistulæ between the ureter and internal organs, the kidney in this case being healthy and easily removed from its capsule.

The cases on the border line must be most carefully studied and reported, and with such care, we believe that nephrectomy will follow the improving path of ovariotomy to equal surgical triumphs.

Resection of a rib has been done in two cases in order to give greater room. Czerny once resected the eleventh and once the twelfth rib, both successfully. Barker, however, has shown that it adds little to the advantages of the operation and Dumreicher in prolonging his incision to what he took to be the twelfth rib, really reached the eleventh (the twelfth being rudimentary), opened the pleura and death followed from collapse of the lung.

The results thus far have been encouraging for so new and so serious an operation. Of the 76 cases 40 have recovered, 33 died, and 3 were under treatment. The results of the two methods of operation are, on the whole, largely in favor of the lumbar operation, doubtless from the nature of the cases suitable to it. The lumbar operations number 38 with 14 deaths, 36 per cent.; the ventral 33 with 19 deaths, 60 per cent. In 5 cases the result is yet undecided or the incision not stated. The mortality of the abdominal operations is, however, increased unduly by the fact that about half of them were undertaken with a false diagnosis. Not a few of them were unsuitable for operation and would not have been interfered with had the real nature of the case been understood.

THE PHYSIOLOGY OF THE SPLEEN.

IN spite of the numerous and valuable studies of which the spleen has been the subject, its function, with that of the other so-called ductless lymphatic glands, still remains involved in considerable obscurity. Its inclusion in the group of blood-making organs has been established beyond doubt, and Schönfeld and Tarschanoff have described its periodic changes in bulk, a relation being found by the former between changes in volume and changes in blood-making activity, while the latter, as well as Setschenoff and Sabinsky, have traced the relations between the size of the organ and various conditions of nerve influence. Some recent studies undertaken by Dr. Chas. S. Roy, on the characteristics of the normal splenic circulation, and the vaso-motor mechanism of the organ, published in the *Journal of Physiology*, January, 1882, promise to throw considerable light on this subject.

Dr. Roy's method consists in enclosing the spleen in a rigid metal box, of appropriate shape, filled with oil, and of such a construction that, while no hinderance is offered to the entrance and exit of blood by the splenic arteries and veins, any change in the volume of the organ causes a rise or fall, corresponding in extent, of a recording lever writing upon the moving paper of the kymographion.

Dr. Roy finds that the spleen is continuously contracting with a rhythm which, in so far as the element of time is concerned, is remarkably constant, averaging about sixty contractions an hour in the case both of dogs and cats. The extent or volume of the splenic systole is, however, subject to great variations. For although no pulse wave is evident, and only slight indications of a respiratory wave, the force of the muscular contractions, and hence the quantity of blood expelled from the spleen vary considerably. It is also interesting to note that, even when the general blood-pressure in the organ is greatly diminished, as by closure of the aorta, there is only a partial reproduction of the change in the spleen volume, indicating that the passages by which the blood enters the spleen are comparatively narrow, and that the mass of blood in the organ is practically cut off from the arterial system, and that, therefore, the circulation through the organ must be carried on almost exclusively by the rhythmical contraction of the smooth muscular fibres of the splenic capsule and trabeculæ, and not by the general blood-pressure. These experiments, therefore, indicate the existence in the spleen of a function hitherto unsuspected: that of propulsion of its own circulation; while they also show that the splenic systole may be an important element in the maintenance of the portal circulation.

As regards the vaso-motor mechanism of the spleen, Dr. Roy finds that stimulation of the vaso-motor centre, as by asphyxia, or direct stimulation, as has been pointed out by Tarschanoff and Setschenoff, causes a rapid contraction of the spleen, which Dr. Roy shows is not due exclusively to a contraction of the walls of the arterioles, but also to the contraction of the special muscular fibres of the organ. Reflex stimulation of the vaso-motor centre by stimulation of the central end of a sensory nerve, even after division of the splanchnics and vagi, produces analogous results, as also follow stimulation of the peripheral end of either splanchnic or vagus, though there does not appear to be any splenic vaso-motor "*tonus*" passing along these nerves, as their section is not followed by an expansion of the organ. These results also show that there must be a fifth path for the vaso-constrictor influences from the cerebro-spinal centres; and since section of the vagi and splanchnics does not interfere with the splenic rhythm, there must be some special mechanism in the organ itself by which its systole and diastole are regulated.

The importance of these investigations, and particularly the value of his method, is evident, and we trust soon to see the publication of his results on the action of different substances in the blood on the splenic circulation, as well as his deductions as to the bearing of these observations on the general physiology of the spleen.

THE PUBLIC INFLUENCE OF THE MEDICAL PROFESSION.

A PROFESSION so numerous, so well educated, and of such social and personal influence as ours, ought to exert a telling influence in questions affecting the public health. That it does not, is only too certain and too well known.

The reason why it does not is evident even to a superficial observer. No organized public effort is made to give voice to the opinions of those best qualified to direct municipal, State, or national action in such matters. Our medical societies hold their meetings privately, uninvaded by the otherwise ubiquitous reporter. No matter how valuable and striking the paper that is read, not the faintest echo is heard in the daily press, and yet it may be pregnant with truths the people should know, and treat of evils that are to be remedied, not by private admonition to individual patients, but by public legislation by bodies made up of non-medical men. Only in the medical journals are such papers published, read only by medical men, and then forgotten in the rush and hurry of the daily bread-winning work. Of course, we would not advocate the publication in the lay press of most professional papers. Not to speak of the seeming seeking for notoriety which often might fall into charlatanism, the object of such communications is chiefly our own instruction, and their subjects are often either unfit for general reading or uninteresting from their technicality. But we see the greatest propriety and advantage in giving publicity through the daily press to papers whose object is the destruction of municipal abuses that affect the public health, such as the condition of our streets and of our sewerage systems; the introduction of reforms, such as public supervision of house-drainage and plumbing; the prevention of diseases, such as small-pox, syphilis, and scarlet fever; the improvement of present methods of life in dress, food, nursing, bathing, care of the sick, care of children; the influence of school-life in the health of our millions of public and private school children, and many other subjects that will occur to our readers. On all or nearly all of these, the profession which knows most about them, nay, almost the only one which knows really anything about them, has no more public influence than so many lawyers, ministers, or merchants.

We hope, however, that better days are at hand. The action of the Philadelphia County Medical Society, in investigating the eyesight of our public-school children, and the pending public action on legislation as to syphilis, are steps in the right direction; while our brethren in New York, under the potent influence of Dr. Fordyce Barker, have also taken steps to make their influence felt. When the streets of that city last winter were active breeders of pestilence—and in what large American city are they not?—the voice of the medical profession, assembled as was eminently proper in a public meeting, was lifted in protest; and but a few weeks ago the *Tribune* gave an account, three columns long, of the meeting of the Academy of Medicine, at which Mr. C. F. Wingate, a Sanitary Engineer, read a paper on "Practical Points in Plumbing," followed by a discussion by Drs. Barker, Doremus, Parker, Janeway, and others.

Massachusetts, too, has destroyed the ancient abuses of the coroner, and has substituted the admirable system of medical examiners, chiefly through the influence exerted by the medical profession and the vigorous efforts of the *Boston Medical and Surgical Journal.*

We hope these good examples are but the forerunners of vigorous action. Not as theorists in speculations as to the influence of germs or malaria, not as Don Quixotes riding at every municipal windmill, but as thoroughly practical men, with the burden of the public weal upon our shoulders, surrounded by evil habits, evil traditions, evil modes of life, which it is our duty to better, let us speak, and speak loudly, and speak until we are heard.

Until some such public expression is given to the united opinion of the profession, we can do but little towards improving the public health and destroying the crying evils that exist on every hand. Not till then shall we do our duty as medical men to the public that will hear us if we will but make ourselves heard.

A SURGICAL MILLENNIUM.

IN the last volume of the *Medico-Chirurgical Transactions*, Mr. Spencer Wells gives the brief histories of two hundred cases of ovariotomy, completing one thousand cases upon which he has operated! A history like this is so novel that it deserves more than a mere statement. It is rare for any surgeon to do even a thousand ordinary operations, but a thousand operations such as ovariotomy, put him in a category apart from his fellows.

America anticipated him in the inception and early practice of ovariotomy, and Philadelphia and New York had no mean share in perfecting the operation; but we must all confess that to-day ovariotomy owes more to Spencer Wells than to any other one man. This one operation will make him famous for all time.

A review of such a useful life must be an immense and abiding satisfaction to him. He can well answer Mr. Mallock's question "Is life worth living?" His head never rests upon his pillow without the blessings of hundreds whose lives have been spared through his skill, and of thousands in whose hearts and homes he has made the noon-day sun to shine again. Twenty odd years ago, when he reported

his first modest roll of five cases, the ovariotomist was considered by many as an ogre, a murderer, deserving of indictment by law, a surgical pariah. But Mr. Wells has lived to see seven hundred and sixty-nine women snatched from the grave, and restored to useful and happy lives, the operation firmly established, and the mortality fall in his own hands from 34 to 11 per cent., and with a few operators even to 3 per cent. On the basis of the expectation of life of these one thousand patients, according to the English Life Insurance tables, Mr. Wells has added an aggregate of 17,880 years to human life; or considering only those who have recovered, he has given them 22,880 years of average health and happiness instead of the 3080 years of suffering and sorrow, which they would have had without the operation of ovariotomy. What a benefactor such a man is to the human race! What an ornament to his time, his country, and his profession! *Serus in cœlum redeat!*

It is to be hoped, in the interests of science and of medical progress, that the anti-vivisectionists will continue in their present course of indiscriminate and illogical attack upon every prominent member of the profession against whom they can find or invent a pretext for directing their puerile abuse. After having picked up Mr. Jonathan Hutchinson on a charge of allowing a case of pemphigus to remain three days without active treatment, in order that it might thereby be made more instructive to the students, and having dropped him rather precipitately as being intellectually too warm for their handling, they have now flooded the papers with silly trash about the "unnecessary" experiments with aconitine upon mice, made by Drs. Dupré and Stevenson, in the Lamson case. As a London contemporary remarks, the grievance is not the cruelty of the practice, but the audacity of science "in venturing to do that in a questioning spirit which every housemaid is thought justified in doing under the plea of convenience, cowardice, or caprice."

Argument is wasted upon such persons, and vituperation would reduce us to their level. "Come, then, expressive silence!"

We are gratified to learn, from the London medical journals, that the authorities have refused to comply with the demand of the counsel of "Dr." Lamson, the defendant in the now celebrated aconite poisoning case, that an analyst might, on the part of the prisoner, examine the viscera of the deceased. Our gratification is due, not to any ill-will towards the accused, although there is abundant evidence that he was, to put it mildly, an unqualified and unscrupulous practitioner, but to the fact that the principle involved is that which underlies the whole system of medical expert evidence. Professional testimony in all cases, and especially in those implicating human life, should be given neither for defence nor prosecution, but at the request and for the benefit of the court, and by men of such known skill and probity that their statements as to technical points will be unquestioned. To the present system of employing medical men as partisan witnesses, is due much of the popular opprobrium cast upon the profession, the members of which certainly never appear to less advantage, or inspire less confidence, than when contradicting one another in the witness-box. Our own self-respect should urge us to advocate a change, and to approve such action as the court has taken in this case.

At the last meeting of the College of Physicians of Philadelphia, the most recent acquisition of the Mütter Museum, a series of twenty-four coronal sections of the brain, was exhibited, and elicited great interest and admiration. They proceed regularly from the anterior to the posterior surface of the brain. Each is beautifully mounted in a circular glass cell on a square plate of glass, so that both surfaces of each section or slab of the brain are visible, and the whole series is contained in a handsome locked case. The sections are preserved by Müller's fluid, and mounted in carbolized glycerin jelly, and are prevented from disturbance by a spring of whalebone, which gives gentle support. The preparations are the work of Dr. H. D. Schmidt, of New Orleans, and reflect the greatest credit upon his skill. They will be of especial value to students of the anatomy and physiology of the brain, and in locating any of its lesions in disease. The physicians and medical students of the city should be more familiar with the many and accumulating treasures of the Mütter Museum.

"My wife," said Rev. Dr. Robert Collyer, at a recent meeting of the Brooklyn Maternity, "my wife is a prudent woman, and never praises me to my face, but she would tell you, I know, that as a nurse I am worth 80,000 trained nurses rolled into one." Aside from the preposterous exaggeration, the fact is that Dr. Collyer is *not* as good as a properly trained nurse. A husband, a wife, a daughter, may be moved by their deep affection to the utmost fidelity, but faithfulness can never replace knowledge. Indeed it is high time that the public should appreciate the fact that such earnest affection is generally a serious bar to the best service; for the greater the love the greater the anxiety, and the greater the anxiety the less the judgment, and on good judgment the patient's life may depend. A conscientious nurse will be as faithful as the most loving husband, and will have what he cannot have,

even if he "has had nine children," as the papers make Dr. Collyer say he has, and that is the trained eye and ear and hand, and above even them the skill and tact founded on teaching as well as experience. Nice appreciation of a patient's wants and needs and dangers require an unbiassed mind. Hence doctors rarely attend their own families, and hence skilled nurses are better than the best amateurs.

We are glad to learn that at the March meeting of the College of Physicians, it was definitely determined to establish a Directory for Nurses in Philadelphia, substantially on the plan of the Boston organization. A committee, consisting of Drs. W. W. Keen, Albert H. Smith, and S. Weir Mitchell, was appointed to organize the Directory as speedily as possible, and to take the necessary steps to fit up rooms on the first floor of the College building as an office and residence for the Secretary of the Directory. So soon as the Directory shall be established, we trust that it will receive the heartiest support of the profession throughout the city and the neighboring towns.

In an editorial on the subject of nerve-stretching in our issue of February 18, we spoke of the success had by Billroth and Nussbaum in bloodless nerve-stretching. We learn from a letter to the *Lancet* of February 11, that Prof. Trombetta, of Messina, first used this method in June, 1880, and, in July, 1880, published an account of it in a monograph.

REVIEWS.

Diseases of the Rectum. By William Allingham. *Fourth Edition.* 8vo, pp. 332. Philadelphia: Presley Blakiston, 1882.

This treatise on fistula, hæmorrhoids, ulcer, stricture, prolapsus, and other diseases of the rectum, has been long and favorably known; the chief interest in the present edition lies in the certainty which it affords that more enlarged and extensive experience has not materially modified the views of the author as to the main points involved in the diagnosis and treatment of the various diseases of which he writes.

Probably the point of most general interest, as being still under discussion, is the treatment of internal hæmorrhoids and the comparison of the various methods as to safety and efficiency.

After a careful consideration of these operations, including excision, the use of the écraseur, the application of caustics, the injection of carbolic acid, the galvanocautery, the clamp and scissors with the actual cautery, dilatation of the sphincters, removal by the screw-crusher, and ligation, he gives his unqualified approval to the latter method, which he has employed 1600 times without one fatal result. He quotes from many eminent authorities in support of this position, and adds that he does not think that "in the whole range of surgery there is any procedure worthy of the name 'operation' which can show a greater amount of success or smaller death-rate than the ligature of internal hæmorrhoids." He speaks with almost equal force of the value of linear cauterization in procidentia recti, a method devised by Dr. Van Buren, but which the author has employed in a large number of cases. He very properly rejects the theory of M. Gosselin, supported by Dr. Erskine Mason, that rectal stricture is generally a result of chancroidal ulceration, and is disposed to attribute it in about half the cases to organization and contraction of a late syphilitic deposit, in the others to various local and constitutional conditions.

The book is still, perhaps, with the exception of Dr. Van Buren's treatise, the best guide in the diagnosis and treatment of rectal diseases in the language. Its typography and general appearance are, as usual, highly creditable to the publishers.

Contribution à la Therapeutique Chirurgicale des Fistules Vesico-Vaginales (Contribution to the Surgery of Vesico-Vaginal Fistulæ). By Dr. Cazin. Reprint from the *Archives Générales de Médicine*, March and April, 1881.

The author gives four interesting cases. In the first he practised Lallemand's method of producing granulating margins by the thermo-cautery, and then on the twentieth day uniting them by wire sutures. The second and third cases are illustrations of a process which he terms "autoplasty by mobilization of the posterior wall of the vagina," a very ingenious method, applicable to very large fistulæ. First, the margins of the fistulæ are pared; next, the posterior wall of the vagina is dissected from the rectum in a flap which is cut through at its superior as well as, of course, at its inferior margins, while laterally it is left adherent to the recto-vaginal septum. The margins of the fistulæ and those of the flap are then united by sutures, thus closing the aperture. In order to support this displaced flap and to prevent strain on the sutures and contraction, he introduced a condom into the new vaginal path thus made, and distended it with air, replacing it later by a Gariel pessary. The result was completely successful. Satisfactory coitus was also possible, but he warned his patient that pregnancy must not follow. In the last case, æt. twenty-three, the fistulæ was attended with such contraction of the urethra and the vulvar outlet, that he deemed it better to close the vagina entirely, and after making a recto-vaginal fistula, to utilize the rectum as a bladder, fæces, urine, and the menstrual fluid all passing per anum. The urethra had already so contracted that nothing escaped by it, and to close the vagina was a matter of little difficulty. The result was most excellent. So many cases of this use of the rectum have now been reported that there can be no question of the entire propriety of it in suitable cases. In this country, Keen (Toner Lecture, No. V., 1876), Goodell (Lesions in Gynecology), and others have related very striking and successful cases, which should encourage further attempts in the same direction.

Ueber Nasenblutung, Nasentamponnade und deren Beziehungen zu Erkrankungen des Hörorganes.

On Epistaxis, Tamponning the Nose, and their Relations to Diseases of the Ear. By Dr. Arthur Hartman. Reprint from Knapp & Moos' *Zeit. für Ohrenheilk*, vol. x., 1881.

It is to be feared that in most cases of epistaxis an exact diagnosis as to the locality whence the bleeding comes is rarely made. The author teaches both didactically and clinically that careful examination may, and in most cases will, afford us a precise indication as to the source of the hæmorrhage. This occurs fortunately

most frequently from the front part of the nose, and especially from the septum or the floor of the naris, and rarely from the mucous membrane over the turbinated bones. If the exact source of the hæmorrhage can be discovered, he advises a tampon of absorbent cotton applied directly to the bleeding spot with pressure, or if a precise diagnosis cannot be made, that the naris be plugged with the cotton. He is averse to plugging the posterior naris with cotton, and especially if it be saturated with the liquor ferri sesquichloridi, not only on account of the disagreeable procedure necessary, but because of the liability of producing middle-ear disease, of which he gives three illustrative cases.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 2, 1882.

FORDYCE BARKER, M.D., PRESIDENT, IN THE CHAIR.

THE paper of the evening, by FREDERICK A. CASTLE, M.D., was entitled:

Some Practical Suggestions in the Treatment of those Diseases of Women which every Physician may be called upon to Consider.—Dr. CASTLE apologized for formally appearing before the Academy to read a paper embodying points so disconnected, and apparently so trivial; but still, from the standpoint of the general practitioner, he hoped the time thus spent would not be entirely lost. Most physicians in general practice frequently have occasion to prescribe for women between thirty and fifty years of age, who are approaching the menopause. The troubles of which they complain are, for the most part, considered to be digestive. Almost the only account of the nervous phenomena incident to this period is to be found in the writings of Dr. Sidney Ringer, and is so graphic and truthful that he quoted it. Dr. Ringer extols the use of amyl nitrite in the treatment of these cases.

Dr. CASTLE had not used small bleedings or purgatives. He had tried the bromides, and found that large doses were necessary to allay the symptoms. He had tried amyl nitrite, but some four years ago began the use of arsenic, *liquor potassii arsenitis*, and had found it so efficacious that he had used it in every such case that had come under his care since that time. He did not know who originated this treatment.

The next subject considered was that of uterine displacements, which he confessed to some hesitation in calling attention to. No systematic writer, so far as he knew, had spoken of over-distention of the abdomen with flatus as a cause of prolapsus of the uterus; this he considered to be not an infrequent cause, and should be borne in mind in dealing with these cases.

That class of cases in which a retroverted or retroflexed uterus became attached to the anterior wall of the rectum by adhesions, was next referred to. The symptoms of this condition resembled those of stricture of the rectum. He had also noticed, as a symptom, periodic hæmorrhages taking place from the vagina.

The author of the paper demonstrated how, by oiling a hard-rubber pessary, and holding it over the flame of an alcohol lamp, it could be moulded into any desired form. He claimed originality for changing an ordinary hard-rubber Albert Smith retroversion pessary into an anteversion pessary by this means.

Dr. CASTLE next spoke of vaginal douches, and recommended as the most feasible method of irrigating the vagina, to have patients take a sitz-bath, and while so doing, inject with a syringe the water of the bath.

Dr. HANKS thought the points alluded to were of a practical nature. He was particularly interested in the first suggestion made, for he had found some difficulty in relieving the nervous troubles so frequently met with in women past forty years of age and under fifty. He was very happy to hear of a remedy he had never used, and would not fail to give it a trial.

In reference to one of the causes of prolapsus and retroversion of the uterus being a condition of intestinal indigestion, he thought many could bear testimony to the truthfulness of that statement. He had frequently found this causative factor among dispensary patients. When prolapsus existed, he usually found the patient the subject of constipation, indigestion, or dyspepsia. In regard to hæmorrhage being a symptom of retroversion of the uterus with fixation, he would say, that it might be present one, two, or three months, but after the inflammatory symptoms had subsided, it would cease to exist. In the treatment of these cases great care should be given to keeping the bowels regular. Applications of iodine were useful.

With reference to pessaries, Dr. HANKS said, I find the short anteversion pessaries, which simply pass up in front of the uterus, of little use, and in the vast majority of cases these so-called short anteversion pessaries do much harm when left undisturbed for a fortnight. From a long experience in Demilt Dispensary, and a somewhat shorter experience in the Woman's Hospital, and from my own private practice, I am *sure* I can successfully treat all cases of anteversion without pessaries, except when the anteversion is accompanied by prolapsus in the first degree. I am well pleased with the use of Thomas's *hinge-saddle* pessary, and I believe others will find it effectual. This pessary to which I refer is an Albert Smith, with a second piece for the cervix to set in, hinged to its wide extremity. It raises the uterus from the floor of the vagina, at the same time correcting the anteversion.

Dr. PAUL F. MUNDÉ said these minor details of gynecology form an interesting chapter, and to them he had given, for some years, a good deal of attention. The speaker referred to a lawsuit for damages brought by a lady about forty years of age, who had been the subject of a railroad accident. The symptoms of which she complained were those peculiar to the menopause. Being called to testify in the case, he attributed the symptoms as those incident to and dependent upon the menopause. Only three days previous, a case of tinnitus aurium was brought to him for examination of the uterus, in which that organ was supposed to be at fault. Upon examination no such difficulty was found to be present. Hence, he thought, care should be taken not to attribute too many nervous symptoms to the menopause. He thought the author of the paper laid too much stress upon dyspepsia and flatulence as a cause of prolapsus of the uterus. In dealing with adherent retroverted uteri, he had found that they gave rise to bearing-down pains, but he had never observed ulcerations.

Several years ago he modified the Albert Smith pessary as suggested by the author of the paper, and found it served an excellent purpose in cases of cystocele with a considerable degree of prolapsus. He had also found it was not without its dangers, for one of his patients, after wearing it three or four months, returned to him complaining of a good deal of pain, and upon examination it was found that the pessary was deeply imbedded in the vaginal walls. This is the trouble with all pessaries of a similar kind, except they were so soft as to yield to the pressure of the tissues. He had changed the hinge of Thomas's latest anteversion pessary, furnished with an open cup, sinking it into the bulk of the pessary. With this he was exceedingly well pleased. A patient of his had been wearing one of these pessaries for two years, taking it out every night and replacing it in the morning. It supports the fundus well and does

not get displaced. But there were two objections to it, one was it would produce abrasion of the anterior wall of the vagina, the other was that the menstrual discharges get in between the uterus and the cup, and give rise to a foul odor.

As to plugging the central hole of the nozzle of a vaginal syringe with a match, as recommended by the author of the paper, he had suggested that some seven years ago in a paper already published. He did not agree with Dr. Castle that the vagina was not an absorbent organ. It did not absorb as well as the rectum, but he obtained the soporific effect of the bromide of potassium when introduced into the system by vaginal injections. A certain amount of the injection would necessarily come in contact with the cervical mucous membrane, and that was more absorbent than the vaginal mucous membrane. As an evidence of its absorbent qualities, he cited the fact that a few minutes after applications of iodine to it, that drug could be tasted in the mouth.

Dr. THOMAS ADDIS EMMET said, I regret, Mr. President, that I arrived too late to hear the first part of the paper, and will hence confine my remarks to one point—displacements and pessaries. I think a great deal of the difficulty due to the fact that a correct diagnosis is not made to begin with. A great deal of ingenuity is wasted by not appreciating what we wish to do. I regard anteversion of the uterus as not a malposition of the organ. As to diagnosis, one of the commonest errors, I think, is neglecting to examine by the rectum, and to discover inflammation behind the utero-sacral ligaments. A very small amount of inflammation existing there, even though it may not produce extreme anteversion of the uterus, will produce symptoms recognized and attributed to displacement of the uterus. If inflammation exist behind the uterus, and we attempt to apply a pessary, and we cannot recognize this condition through the vagina, we will be disappointed in the use of any pessary. Another important point is to know whether to reduce a displacement or not, if any exist. The first impulse coming into the mind would be, probably, if the uterus be prolapsed, retroverted, or anteverted, to correct its position. To do so is, in my experience, one of the commonest of errors. If we have this inflammation behind the uterus, we have shortening of both broad ligaments, and the uterus must be retroverted or anteverted, and under these circumstances our pessary will do no good; but, on the contrary, a great deal of harm; so it is important to know just when to reduce a displaced uterus. If we can lift the uterus but a trifling distance, we can relieve all the symptoms attributed to anteversion, even though we antevert the uterus still more. This can be done by a pessary with a long enough curve in the posterior culde-sac, so as to lift the neck of the organ from the floor of the pelvis. If due to inflammation behind the uterus, a pessary will increase the difficulty. These cases are exceedingly difficult to treat if we cannot prevent the uterus coming forward. One point necessary is to make it a little wider than the vaginal outlet; or use a small India-rubber disk or plug of cotton—something that will raise the uterus just enough to restore the circulation. It matters very little what pessary is used, as long as you have a clear idea of what you want to do with it. With a very simple instrument the indications can be fulfilled, if it is but a pledget of cotton.

In regard to vaginal injections, I would simply say that if a woman will not take them lying down I would prohibit her using them. The position is of as much importance as the hot water. You must make use of posture to get rid of the engorgement. You might as well treat a case of varicose veins of the leg with that member hanging down. After a patient has remained in position, with her hips higher than the rest of her body, for a short time, use the douche, and you will give tone to the vessels. Much harm comes from the use of the vaginal douche in the upright position. I always direct my patients to pass the nozzle of the syringe to the opposite side from where the cellulitis is.

Dr. WM. T. LUSK said it was his misfortune to have heard only a small portion of the paper which had been read, hence he would base his remarks on the discussion which followed. About ten years ago, Shultz wrote an article in which he said that an anteverted uterus never gave rise to symptoms until the utero-sacral ligaments were involved. He liked the anteversion pessary shown by Dr. Castle. Anteversion pessaries could not be safely worn without removal from time to time. Excessive stretching of the vagina might give rise to local peritonitis.

The PRESIDENT, being called upon for remarks, responded, saying he would venture to discuss a few points brought out in the paper which seemed of great practical value, bearing upon just those questions which every practitioner is called upon to treat sometimes. First, in regard to functional disturbances associated with the menopause. He met with this class of patients almost every day. As to the remedies, the author of the paper had referred to purgatives, laxatives, and small bleedings. Now this form of treatment is very useful. He had not resorted to small bleedings. Purgatives administered once in about four weeks, to take the place of the drain which the system has been accustomed to for thirty or forty years, were very beneficial, especially in cases where there is a tendency to plethora. With some women, who up to this age have been thin, there is a tendency to get stout and fat. At periods corresponding to the time of the menstrual flow, they would have attacks of sleeplessness, palpitation of the heart, waking up at night with a feeling as if the heart's action would stop, which was owing to accumulations within the system not relieved by periodic flow. At these times a saline laxative administered for a few days acts well. But there was a class of cases in which such treatment would be worse than no treatment. These were patients with cold extremities and flushed face, due not to congestion but to exhaustion—vaso-motor disturbances. It is in this class of cases that the bromide of potassium, combined with tonics, is excellent. As to arsenic in these cases, he believed many present must have heard him recommend it as long ago as fifteen or twenty years. In some of these cases, we are apt to have small hæmorrhages from the vagina, amounting to very little in the aggregate, but continuing for days or weeks. For these he considered Fowler's solution of arsenic almost a specific. He thought it was a mistake made by most practitioners to regard the uterus as having a fixed locality. The position of the uterus is constantly changing, according to the condition of the bladder, intestine, and rectum. When we attempt to treat this condition, and establish a fixed theoretical point by means of instruments, he thought we were very apt to overlook this change in position, which was normal and physiological. For many years, when he had found a case of retroversion or prolapsus of the uterus, he had inquired into the condition of the digestive organs. By attention to the digestion, the removal of flatus, and correcting the condition of the bladder, many of these cases were relieved. In regard to pessaries, he would say he had never introduced one but twice; these were in old ladies suffering from cystocele.

Dr. CASTLE closed the discussion, and the Academy adjourned.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, March 2, 1882.

RICHARD A. CLEEMANN, M.D., IN THE CHAIR.

Mechanical Dilators in Gynecological Practice.—Dr. CHAS. H. THOMAS stated that he had used the Ellinger dilator, and had been very much annoyed by a bad fault in the form of the blades. As soon as the instrument is opened, the uterus shows a strong tendency to slip away from the dilator. This is due to the form of the outside edge of the blades, which gives to the dilator a wedge shape, with a difference of ten millimetres between the measurements of the base and apex. Conicity in uterine dilators is a dangerous quality; the instrument tending to slip in the direction of the base of the wedge. If the dilator, when in use, slips out of the grasp of the cervix, it is likely to produce laceration; while if it slip inward, as most dilators tend to do, it will wound the fundus uteri.

Dr. B. F. BAER made the following remarks: I am glad that Dr. Thomas has alluded to some of the defects of Ellinger's dilator. I have found the same objections, and have tried to overcome them by having an instrument so made that the mechanism by which the blades are separated is placed in the blades themselves, close to their points, and entirely concealed when they are in contact. This gives great power to a *small* instrument, and as the outer surface of the blades is perfectly parallel, and cannot feather, because of the position of the separating mechanism, the instrument does not slip out. I do not now need a tenaculum to hold the cervix in place, which is a great advantage. I have also had the handles bent down, so that I can see just what the instrument is doing; and, by a screw, so placed that it can be worked on the left, with the left hand, whilst the right hand holds the handles and separates the blades, the dilatation can be done slowly and deliberately, with less tendency to slip out, and with less pain than with the old instrument.

With regard to the result of dilatation of the cervix for the cure of sterility, my experience is based upon the treatment, by dilatation with the steel instrument, of more than two hundred women who were sterile because of a defect in the calibre of the cervical canal, either from stenosis or flexion, resulting from imperfect development. Where the sterility was the result of obstruction, dysmenorrhœa was almost invariably present. This experience leads me to the conclusion that, although the canal is made so patulous by dilatation as to markedly improve the dysmenorrhœa, and in many cases to cure it permanently, the sterility remains in the vast majority of cases, if the patient has been married more than three years before coming under treatment; and if she had attained the age of twenty-six or twenty-seven years before marriage, then, though she come under treatment immediately afterwards, she will very likely be sterile. This will apply to the great majority of cases, but not to all. I think the reason may be stated as follows: The long-continued hyperæmia of the uterus, the result of dysmenorrhœa, which probably existed from puberty, and especially from the non-fulfilment of the sexual function by conception, gives rise to such changes in the histological elements of the uterus that, instead of the organ being muscular, and, therefore, possessing its natural resiliency, elasticity, and suction power, it is hard, fibrous, and non-elastic. The mucous membrane lining the cavity also becomes so changed in its character that, if fecundation should take place, there is not a proper nidus furnished for the reception of the ovum, and it passes off without forming an attachment. The tissues of the Fallopian tubes are likewise changed, and the tubes narrowed in consequence. This might explain the persistence of the sterility after the dysmenorrhœa has been relieved by dilatation of the cervix.

Dr. J. C. DACOSTA has modified the Ellinger dilator by having the blades made very stiff and with a knob at the extremity, as in the uterine sound. When necessary he makes use of counter-pressure over the fundus. In some cases he uses a small instrument first, to enable him to introduce the more powerful one through the internal os.

Respecting the statement of Dr. Baer as to the incurability of sterility of three years' standing. He had recently had under treatment a lady, who had one child seven years ago, but had since been sterile; the uterus was sharply anteflexed; a dilator was used for the relief of the flexion, and three months later the patient exhibited all the early signs of pregnancy.

Dr. BAER remarked that this case was not one of the class to which he had alluded. This patient had had a child, and anteflexion, probably the result of sub-involution and endometritis, was the cause of the sterility. Failure occurs in cases which have never been pregnant, and in which the uterus is enlarged, hard, and changed in its histological character. He thinks it desirable to avoid multiplicity of instruments, and to have one dilator small enough to enter any os, and so arranged as not to yield to any pressure, but under all circumstances to preserve the parallelism of its blades.

Dr. THOMAS thought that one reason why the sponge-tent did good work, was because it worked slowly and continuously. Four years ago he made drawings of a modification of the steel dilator to accomplish the same end. The instrument was made somewhat shorter than the ordinary one; the blades were absolutely parallel on the outside edges and were approximated by means of a screw passing through a slot in one handle, and attached to the other, a milled-head traversed this screw and between it and the handle of the dilator was placed a spiral spring or a soft-rubber pad. This instrument was intended to remain *in situ* for twenty-four hours, the spring making the action gradual and continuous, one or two turns of the screw being given every two hours by the doctor, or a nurse properly instructed. The doctor thought that in this manner he could secure many of the advantages of the sponge-tent, and at the same time avoid its dangers.

Dr. R. P. HARRIS had recently seen in a foreign journal, diagrams of a very neat instrument intended to accomplish the same purpose. It consisted of a C-shaped spring, to the ends of which were attached blades long enough to pass through the internal os. The fingers pressing on the top and bottom of the C, closed the instrument for insertion. Its action would be regulated by the strength of the spring. To obviate the danger of slipping too far into the uterus, a dilator with diverging blades could be furnished with shoulders to rest against the cervix. The divergence of the points of the blades he considers an advantage. The feathering reduces the apparent divergence in use, and that which remains helps to retain the instrument in place, particularly if the blades are furnished with shoulders; the dilating power is greatest where it is most needed, at the internal os. To meet an objection advanced by Dr. Thomas, he suggested that the shoulders might be made movable to suit uteri of different depths. In every case in which a dilator is used, the patient should be kept in bed until the direct effects are over. He had recently under observation a case of dysmenorrhœa, in which the dilator failed, but in which a sponge-tent effected a cure.

Dr. BAER thought the blades should be parallel, and that dilatation should be uniform, without regard to the point of greatest constriction. Too much should not be expected from the dilator; a case of dysmenorrhœa could not be cured by one treatment; it is by the re-

peated use of the dilator at proper intervals that the best results are to be secured. As an instrument, it replaces a set of graduated sounds, and the original inventor must have had that object in view. The contractility of the uterus must be overcome gradually. Even when tents are used, contraction will recur. The advantage of the dilator lies in its comparative freedom from danger, and in being less troublesome to the physician. It is indicated whenever there is constriction from any cause; for if there is not good drainage for uterine discharges, there will surely be irritation, resulting in endometritis.

The effect of the dilator on hypertrophy is the same as with sterility. If of long standing, it is not curable; after the hard fibrous stage is reached, no reduction results from its use. But if the condition is recent, and the enlargement is of the muscular elements, or is due to engorgement, a cure may be secured, because here we have nearly the same condition which exists after labor, viz., a muscular uterus having the power to contract and involute. I do not believe that chronic hypertrophy of long standing will, as a rule, yield to any treatment, but the symptoms to which it gives rise can be relieved to a very great degree in most cases.

Dr. ALBERT H. SMITH regretted that Dr. Baer had not seen the admirable effects of the sponge-tent on uterine hyperplasia. If you use a steel dilator in the uterus, it can remain but a very short time, practically not more than five minutes, giving a sudden mechanical dilatation, accompanied by probable rupture of the hardened fibres of the cervical canal; but it cannot give that stimulation to the contractility of the uterine muscles and to cell action that results from the use of the sponge-tent when no inflammatory action is existing. There is great resistance at first, but after the lapse of forty-eight hours, the internal os and uterine walls have relaxed, spasmodic contraction ceases, and the vital power and muscular contractility of the uterus are developed by the presence of a foreign body which the natural powers will try to expel. Just as you have, after the expulsion of an ovum, a physical atrophy of the uterus, so you will have a similar action set up by the presence of a sponge-tent in the cavity of the uterus. No such result could be secured by the use of a steel dilator; the latter must lacerate and leave surfaces ready to absorb septic matter, while you have not the advantage of the presence of the salicylic acid or other disinfectant present in the tent; the latter, expanding slowly, is not likely to cause laceration. The too early removal of the tent, while the spongioles are fast in the uterine tissue, may leave an abraded surface; but after forty-eight hours the tissues have shrunk away, and the sponge comes away easily. Dr. Smith read the following letter from Dr. Mundé:

"My Dear Doctor: . . . Remembering your remark with regard to the absence of proper dilatation of tupelo-tents, I procured a number from Tiemann & Co., and dilated them in tepid water. I send you by this same post four different sizes, dilated and undilated, and also two perforated, zinc-lined tents, to be worn during the period, for dysmenorrhœa—one before, the other after, dilatation.

"This amount of dilatation was reached within one hour. Certainly no fault can be found with the expansion of these tents, since it will be seen on comparison that all the tents have swelled to fully double their compressed size, and have retained their expansion on being dried. It may be objected that this full dilatation would probably not take place if a resistance were offered as in the uterine canal. While I partly admit this, still I have within a month had reason to use the largest size to dilate a uterus, and secured quite as much expansion, as shown by the accompanying tent. The softness of the wood allows of their being whittled to any size and shape.

"I also send a tent dilated in utero, which shows some contraction at the site of the internal os.

"I presume that the failure of your tents to dilate may have been due to their having absorbed moisture from the atmosphere. They should always be kept wrapped in air- and water-tight paper. Tiemann & Co. tell me that all their tents are compressed to their utmost by machinery.

"As for the other forms of dilatation, I have used the steel, two-branched dilator of Ellinger almost exclusively. I found it too difficult to force the graduated hard-rubber sounds through the cervix if it is virginal and hard. The tenaculum tears out, and the force is too great. I have dilated in hospital and private practice (with two-branched dilators) in about one hundred and fifty different cases, probably some six to seven hundred times, chiefly for dysmenorrhœa and sterility, always in my office or dispensary. I have almost invariably relieved the dysmenorrhœa, temporarily, at least; the sterility but rarely, although my later statistics on this point are meagre. I have but one bad result, pelvic peritonitis, and then curetting and tincture of iodine to the endometrium were also employed, either of which might be blamed. I prefer steel divergent dilators for temporary, tupelo-tents for permanent, results. Slippery-elm-tents dilate but little, but I have found them good in dysmenorrhœa to render the canal patent."

Dr. R. P. HARRIS stated that he is using cylindrical sponge-tents, coated with salicylic acid, which he finds has a local anæsthetic effect on the lining membrane of the uterus.

Dr. A. H. SMITH said that of all the steel dilators which he has tried, he prefers the instrument devised by Dr. T. G. Thomas, in which the blades are separated by being drawn into a cannula by screw action. It is, however, difficult to clean. He has found the handles of Dr. Elwood Wilson's dilators very much in the way when the uterus is anteflexed.

Dr. BAER remarked that he was much instructed by Dr. Smith's remarks. He was surprised at the time—forty-eight hours—that a sponge-tent could be allowed to remain, and at its effect in the disintegration of abnormal tissue without the development of septicæmia. He finds it hard to believe a change could ensue after the uterine walls had been changed to hard fibrous tissue; but experience is the best teacher.

CORRESPONDENCE.

A NEW DANGER IN ANÆSTHESIA.

To the Editor of THE MEDICAL NEWS:

A case similar to the one related by Dr. George Fischer, in the *Deutsche Zeitschrift für Chirurgie*, 1881, vol. xv., p. 188, copied in THE MEDICAL NEWS of February 25, 1882, except, however, its fatal results, came under my observation during the late civil war, and is amongst my most vivid recollections.

Just after the battle of the North Nuna, in May, 1864, an officer was brought into the field-hospital with his arm shattered, and necessitating immediate amputation. Chloroform was administered in the usual way, and every preparation was made for the operation, when suddenly, at the period of complete anæsthesia, respiration ceased, the pulse had nearly gone at the wrist, and there was every indication of immediate death. His tongue was drawn out; exploration was made of the mouth and fauces, and a large quid of tobacco, seemingly as large as a large-size hen's egg, was discovered filling up the entire faucial space, and falling over on the larynx and glottis, and impeding res-

piration. It was removed with difficulty, the patient was resuscitated, chloroform was readministered, and the operation went on to completion successfully.

It would seem almost incredible that so large a piece of tobacco could have remained in his mouth unobserved, but the operation was performed after twilight, in the confusion of a recent engagement, and it had to be done by candle-light—hence the oversight.

S. J. RADCLIFFE, M.D.

WASHINGTON, D. C., March 3, 1882.

NEWS ITEMS.

BROOKLYN.

(From our Special Correspondent.)

THE METHODIST EPISCOPAL HOSPITAL, founded by Mr. George I. Seney, is to be constructed at once. It will occupy a full block of ground in the immediate neighborhood of Prospect Park. The completed structure will consist of ten distinct buildings, fronting towards the north—an arrangement adopted in order to permit of a southern exposure for the pavilion wards; in the centre a four-story administration building, in which also are situated several private wards and rooms, the nurses' dormitories, the chapel, and library; in the rear of this is the accessory administration building, containing the kitchen, laundry, etc.; flanking these are two-story pavilions, one on either side, with their service buildings; upon one side of these are to be placed the operating theatre, in the basement of which will be placed the dispensary, facing the north, and a mortuary building facing the south; beyond these is to be placed a one-story pavilion with its service building; beyond the other two-story pavilion is to be placed in front a children's and orthopedic ward facing the north, and a pavilion for contagious diseases facing the south; upon the farther extremity is the ambulance stable. The ventilation is to be accomplished by a combination of the fan and hot-air systems, a central chimney to communicate with a ventilating flue under each bed; there will also be arrangements for ridge ventilation. The buildings are to be heated by hot-air passed over steam-coils and by open fire-places. The hospital when completed will cost about $500,000, and will accommodate between 150 and 200 patients, allowing 1800 cubic feet of air to each patient. It will be built of brick with brownstone trimmings. The whole arrangement of the institution has been under the personal supervision of Dr. L. S. Pilcher, of Brooklyn, and Dr. A. E. M. Purdy, of New York, and is intended to embody all the more advanced views in the matter of hospital construction.

THE BROOKLYN EYE AND EAR HOSPITAL has also recently purchased a new building, which, with the land, cost them $50,000, one-half of which has been subscribed by Mr. Seney. It will be fitted up and ready for occupation during the present spring.

THE LONG ISLAND COLLEGE HOSPITAL has also been undergoing very extensive modifications—so much so that the original buildings can hardly be recognized. The hospital accommodations are very much increased and the facilities for instruction have been practically doubled.

BALTIMORE.

(From our Special Correspondent.)

WOMAN'S MEDICAL COLLEGE AND TRAINING SCHOOL FOR NURSES.—A Woman's Medical College has recently been incorporated in Baltimore. Associated with the College is to be a women's and children's dispensary and a training school for nurses. The following is a list of the faculty as far as completed: B. Bernard Browne, M.D., Professor of Diseases of Women and Children and Clinical Obstetrics; Thomas A. Ashby, M.D., Professor of Obstetrics and Clinical Gynecology; Randolph Winslow, M.D., Professor of Surgery; Eugene F. Cordell, M.D., Professor of Materia Medica and Therapeutics; Wm. D. Booker, M.D., Professor of Physiology; Robert B. Morison, M.D., Professor of Chemistry, Urinary Analysis, and Toxicology; Herbert Harlan, M.D., Professor of Anatomy and Clinical Surgery. The Chair of Practice will shortly be filled. The first course of lectures will begin October 1, 1882.

VIENNA.

(From our Special Correspondent.)

NOTES ON GYNECOLOGY.—Dr. M. Funk, Privat Docent, University of Vienna, Das Allgemein Krankenhaus, condemned severely a number of gynecological procedures common in England, but more especially practised in the United States.

Pessaries.—The universal and generally indiscriminate use of pessaries for all varieties and conditions of uterine versions and flexions, he censures as bad practice. Upon the employment of pessaries in this class of uterine disorders, he says:

1. In the great majority of cases, the abnormality, if it really be abnormality, cannot be corrected by the support of a pessary of any kind.

2. If the pessary be at all effective, it must cause so much pain, that it cannot be worn with any degree of comfort.

3. When correcting the position of the uterus, a pessary acts as a ligature around the cervix, impedes circulation and nutritive processes generally.

4. In a number of cases, he has observed the site of a pessary to be the starting-point of a carcinoma, though he is not at all a believer in the traumatic origin of that disease.

The Sound.—He objects to the use of the sound, so generally, as a means of diagnosis, as, also, to the too frequent introduction of the speculum. He claims that abdominal palpation, with digital examination sufficiently varied, is amply sufficient for the diagnosis of most uterine and vaginal disorders. The introduction of the sound he regards as invariably injurious, and in private practice rarely uses the instrument.

While upon the subject of speculums, Dr. Funk alluded indignantly to the assumption of Dr. J. Marion Sims, of New York, to the invention of the "duck-bill speculum." Metzler, of Prague, in 1846, used the same instrument which Dr. Sims claimed as original in 1850.

UTERINE AND VAGINAL CARCINOMA.—Dr. Funk has studied for many years, and under the most favorable auspices, the etiology of all forms of vaginal and uterine carcinoma. He sums up the results of over twenty years' observation, as follows:

1. Syphilis has no causative relation to cancer n these localities whatever, though I have seldom seen the coexistence of the two diseases.

2. Heredity in uterine cancer car . be shown by the most critical analysis of the cases, which I have seen. This point is one of much practical importance, as I have very frequently been consulted when the subject of matrimony has been discussed. In every case, I believe, I have relieved myself of grave moral responsibility by saying positively, there is absolutely no evidence of hereditary transmission of the disease. This, of course, I believe does not obtain in cancer occurring in other localities.

3. Parturition has been emphasized by Graily Hewitt as a cause of uterine cancer, but I must think entirely without foundation in truth. I have had extraordinary facilities for observation in regard to this point, in the

lying-in wards of Profs. Carl, and Gustav Braun, and Spaeth, and so speak with positiveness.

4. Traumatism is never the origin of cancer. I have seen, it is true, a carcinoma spring from the place where a pessary occasioned pressure. In that case, however, I am convinced the relation was only a coincidence.

5. Acute and chronic inflammation connected with the female sexual organs, of all forms and conditions, occur so frequently in the Viennese prostitutes, of whom you very well know we have great numbers, without eventuating in any more serious disease, that I am convinced they are never the starting-point of cancer.

At present, I am not in a position to offer any theory as to the etiology of carcinoma in connection with the female sexual organs. All I can do is to criticise the asserted causes and await developments.

MILAN.

(*From our Special Correspondent.*)

THE SANTA CATERINA LYING-IN HOSPITAL.—During 1881, in this hospital, there have been 290 deliveries, of which 220 were natural and 70 preternatural. The latter required the performance of 77 operations, as follows, viz.: Reposition of the funis by mechanical appliances, 1; forceps in failure of expulsive power, in the cavity of the pelvis, or at the inferior strait, 22; forceps at or above the brim in cases of pelvic deformity, 6; extractions in pelvic presentations, 6; turning, 12; induction of premature labor, 11; induction of abortion in cases of pelvic deformity, 1; craniotomy, 7 (all saved but 1); evisceration in transverse presentations with impaction, 3 (all saved); craniotomy and evisceration of the trunk, 1 (saved); Porro-Cæsarean sections, 2 (both saved); incisions of the os uteri for rigidity, 2; artificial delivery, 3.

Amongst the 290 cases, there have been 4 cases of eclampsia and 7 of placenta prævia. Nine of the whole died, from the following causes, viz.: Nephritis, 3; heart disease, 1; as the result of a podalic version made by a physician at home, 1; pleuritis, 1; and septic infection, 3.

THE OSPEDALE MAGGIORE.—Here the first successful ovariotomy was performed on October 2, 1881.

PROCEEDINGS OF THE IOWA STATE MEDICAL SOCIETY.—The Thirtieth Annual Session of the Iowa State Medical Society was held in Des Moines, January 25–27, 1882. The Society was called to order by the President, Dr. T. J. Caldwell, on Wednesday, January 25, at 10 A.M., and was opened with prayer by Bishop J. F. Hurst, D.D., after which the President delivered his annual address.

During the session almost fifty members were added to the roll. The total attendance was about two hundred.

The following papers were read, discussed, and referred to the Committee on Publication: "Inversion of the Uterus," by Dr. J. A. Blanchard, of Des Moines; "The Plea of Insanity," by Dr. A. Reynolds, of Clinton; "A Small-pox Hospital," by Dr. R. J. Farquharson, of Des Moines; "Disappointments of Country Physicians in the Practice of Gynecology," by Dr. J. Williamson, of Ottumwa; "Pyelitis occurring during the Puerperal State," by Dr. L. C. Swift, of Des Moines; "Management of the Newly-born Infant," by Dr. G. W. Beggs, of Sioux City; "The Diseases Incident to Military Prisons and the Influences by which they are Modified," by Dr. Wm. Watson, of Dubuque; "Operative Procedures in Corneal Lesions," by Dr. C. M. Hobby, of Iowa City; "Local Treatment of the Mucous Membrane of the Air Passages," by Dr. E. H. Hazen, of Davenport; "Life—What is It?" by Dr. J. B. Gorrell, of Newton, "Microscopy," by Dr. J. J. M. Angear, of Fort Madison.

The following officers were elected for the ensuing year: President, Dr. D. Scofield, Washington; Vice-Presidents, S. E. Robinson, West Union; H. L. Getz, Marshall; Secretary, J. F. Kennedy, Des Moines; Assistant Secretary, D. McCrea, Council Bluffs; Treasurer, G. R. Skinner, Cedar Rapids.

The following changes were made in the Constitution: Annual meetings shall be held hereafter on the third Wednesday of May in each year, except when the sessions of the American Medical Association include this date. Then the President shall name the day, which shall be within two weeks of the third Wednesday in May.

The annual dues to be paid by permanent members were reduced to one dollar.

The Society adjourned to meet at Council Bluffs in May, 1883.

THE PUBLIC HEALTH.—For the week ending *February 25*, we report the following additional items: Small-pox caused 7 deaths in St. Louis; 3 each, in New Orleans and Hudson Co., N. J.; 2 each, in Omaha, Nebraska, and the District of Columbia; and 1 each, in Detroit and Buffalo. Hudson Co., N. J., reported 3 deaths from cerebro-spinal meningitis; Davenport 2; and St. Louis, Detroit, Buffalo, and Salt Lake City, each 1 death from this cause. There were 9 deaths from diphtheria in Brooklyn, against 23 for the preceding week; 4 in Buffalo and the District of Columbia; 3 each, in Detroit and St. Louis; and 2 each, in Hudson Co., N. J., and San Francisco. It is to be noted that not a death from this disease occurred in New Orleans during the week. There was a slight diminution in the number of deaths from scarlet fever in Brooklyn, where this disease has of late been unusually prevalent. The record of deaths from this cause for the week is as follows: Brooklyn, 27; Buffalo, 9; Hudson Co., N. J., 6; San Francisco, 4; New Orleans, St. Louis, and the District of Columbia, each 3; and Detroit, Davenport, and Omaha, Nebraska, each 1 death. Malarial fever is prevalent in St. Louis, 7 fatal cases being reported in the week. A marked accretion in the number of deaths (10), from puerperal diseases is noticed in Hudson Co., N. J. Of the whole number of deaths (14), in Salt Lake City, 4 were caused by pneumonia, which is 28.57 per cent. of the total mortality; consumption caused only 1 death.

For the week ending *March 4*, the deaths caused by some of the principal diseases were as follows: Of the eighteen prominent cities throughout the country from which reports have been received, death from small-pox occurred in eight. Cincinnati heads the list with 27 deaths from this cause; then in order follow Pittsburgh, 19; Philadelphia, 14; New York, 14; St. Louis, 8; Memphis, 2; Wilmington, Del., Milwaukee, and Dayton, O., each 1 death. Cincinnati, Milwaukee, and St. Louis, each report 2 deaths from cerebro-spinal meningitis, and Indianapolis 1 death from this cause. There has been a falling off in the deaths from diphtheria in Boston, 9 deaths being reported this week, as compared with 14 for the preceding one. There were 13 deaths from this cause in Philadelphia, an increase of 1 over the preceding week; 4 in New Haven; 3 in Indianapolis; 2 in Milwaukee, and 1 each in Providence, Pittsburg, Cincinnati, St. Louis, Charleston, and Savannah. Only five out of sixteen prominent places report deaths from scarlet fever, and in none of them is the disease prevalent: they are Philadelphia, which reports 4 deaths, and Boston, Charleston, Pittsburg, and St. Louis, 1 death each. No reports have been received from New York or Brooklyn. Typhoid fever

caused 8 deaths in Philadelphia; 3 in Pittsburg; 3 in Cincinnati; 2 each in Boston, Indianapolis, and Wilmington; and 1 each in Louisville, Charleston, Savannah, and New Haven. Malarial fever is still prevalent in Memphis, Tenn., and in St. Louis, 3 deaths having occurred in the former city and 4 in the latter, during the week. Providence, R. I., and Wilmington, Del., both report a number of deaths from whooping-cough. Acute pulmonary affections are prevalent in Boston, Philadelphia, and St. Louis. Of the total number of deaths for the week, consumption caused 19.93 per cent. in Boston; 18.76 per cent. in Philadelphia; 24.44 per cent. in Louisville, Ky.; 16.58 per cent. in Cincinnati; 26.66 per cent. in Nashville, Tenn.; 5 per cent. in Memphis, Tenn.; and 3.84 per cent in Wilmington, Del.

HEALTH IN MICHIGAN.—The Bulletin of the State Board of Health reports that, for the week ending February 25, 1882, neuralgia, intermittent fever, bronchitis, consumption, and rheumatism have considerably increased, and that pneumonia has considerably decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending February 25, and since, at 31 places, scarlet fever at 19 places, measles at 9 places, and small-pox at 8 places, in all as follows: at Spalding, Menominee Co. (9 cases), February 21; among the Indians near Spalding (8 cases), February 21, and 22 deaths to that date; at Detroit and Grand Rapids (convalescent), February 25; at Parkville, St. Joseph Co., February 28; in Kimball and Port Huron townships, St. Clair Co., February 28; at Stanton, Montcalm Co., February 28, 1882.

THE MEDICAL DEPARTMENT OF WOOSTER UNIVERSITY, Wooster, O., has been reorganized by the appointment of the following faculty:

Leander Firestone, M.D., LL.D., Dean, Professor of the Medical and Surgical Diseases of Women; Akin C. Miller, M.D., Registrar and Treasurer, Professor of Obstetrics and Clinical Gynecology; Frank J. Weed, M.D., Professor of Principles of Surgery and Didactic Surgery; X. C. Scott, A.M., M.D., Professor of Ophthalmology and Otology; J. E. Burns, M.D., Professor of Diseases of Children; Reuben A. Vance, A.M., M.D., Professor of Operative and Clinical Surgery; [1]Professor of Principles and Practice of Medicine; Theodore A. Weed, M.D., L.R.C.P., London, Secretary and Professor of Thoracic Diseases and Physical Diagnosis; Jamin Strong, Jr., M.D., Professor of Nervous and Mental Diseases; George Mitchell, M.D., Professor of Materia Medica and Therapeutics; [1]Professor of Anatomy; H. C. Foote, A.M., Professor of Chemistry and Toxicology; L. B. Tuckerman, A.M., M.D., Lecturer on Physiology; Demonstrators of Anatomy, Robert D. Alton, M.D., William C. Craven, M.D.

GENEROUS GIFT TO THE COLLEGE OF PHYSICIANS, OF PHILADELPHIA.—Dr. Weir Mitchell has recently presented another thousand dollars to the College, the income of which is to be used for library purposes. By direction of the College this sum has been added to the "Weir Mitchell Library Fund."

COLLEGE OF PHYSICIANS AND SURGEONS, OF CHICAGO.—We understand that Drs. J. J. M. Angear and A. M. Carpenter have resigned their professorships in the College of Physicians and Surgeons, of Keokuk, and have accepted, respectively, the chairs of the Principles of Medicine, and of the Practice of Medicine, in the Chicago College, which has just been organized.

[1] The vacancies appearing in the above list will be filled before the beginning of the session.

GRADUATES IN MEDICINE.—At the annual commencement of the College of Physicians and Surgeons, of Keokuk, Iowa, held February 21, the degree of M. D. was conferred on 122 graduates—the largest class the school has ever had.

At the Annual Commencement of the Medical Department of the University of Louisville, held February 28, the degree was conferred on 96 graduates.

At the annual commencement of the Medical College of South Carolina, held at Charleston on March 1, the degree was given to 19 candidates; and

At the Commencement of the University of Georgia, at Augusta, on February 28, the degree was conferred upon 23 candidates.

ANALYSIS OF ELEPHANT'S MILK.—The birth of Barnum's baby elephant has afforded an opportunity of obtaining the milk of that animal, and Prof. Doremus has made an examination of it. "When first I examined the specimens, they seemed watery," he said, a few days ago, to the reporter of the New York *Tribune*, who interviewed him, "but after allowing the milk to stand, I could not help wondering at the large percentage of cream. The following represents the daily diet of the mother: 3 pecks of oats, 1 bucket of bran mash, 5 or 6 loaves of bread, ½ bushel of roots (potatoes, etc.), 50 to 75 pounds of hay, and 40 gallons of water. The last specimen of milk I obtained exceeded the others in quantity, and would, therefore, be the fairest for a test. It took several milkings to get even these, for the calf would begin to nurse, then stop, and when she stopped, the flow of milk did, also. The analyses of the samples gave the following results:

	First.	Second.	Third.
Quantity	19. C. C.	36. C. C.	72. C. C.
Cream	52.4 vol. p. ct.	58.	62.
Reaction	Neutral.	Slightly Alkaline.	Slightly Acid.
Sp. Gr.			1,023.7

In 100 Parts Weight.

Water	67.567	69.286	66 697
Solids	32.433	30.714	33.303
Fat	17.546	19.095	22.070
Solids not fat	14.887	11.619	11.233
Caseine	14.236	3 694	3 212
Sugar		7.267	7.392
Ash	0.658	0.658	0.629

"It is evident, from these analyses, that the milk approaches the composition of cream. The milk was pleasant in flavor and odor, and very superior in these respects to that of many animals. The fat is a light yellow, resembling olive oil; is very pleasant in odor and taste, is liquid at common temperatures, but solidifies at 10° Centigrade, or 64° Fahrenheit. From whatever standpoint, therefore, we view the lacteal products of these four-footed giants, we are fully warranted in ascribing to it not only extreme richness, but also great delicacy of flavor."

We are glad to learn that Prof. Doremus, while on the visit, during which he made the above analysis, fortunately escaped serious injury from a most unexpected and violent assault by the father of the baby elephant. The elephant seized him around the waist with his trunk, and swung him violently against the side of the room. He owes his escape to the ready aid of the keeper, and suffered only a slight wound in the head. Elephants evidently do not respect professors as they ought to.

"GROUND-AIR."—Few persons realize the important influence on health of "ground-air," that is, the air contained in the soil. Yet, in an address before the Association of German Naturalists and Physicians, last

September, and published in the January number of the *Popular Science Monthly*, Dr. Max Von Pettenkofer states that so great is the porosity of the ground on which we dwell, that "heavy, towering buildings often stand on a soil which is filled to the extent of a third of its volume with air." This air contains not only far more carbonic acid than the air of the atmosphere, but also many deleterious emanations from the soil, which enter our houses, not in small quantities, but, as it were, by wholesale. "While the house is heated in the cold season, and at night in the summer, while the air within-doors is warmer than the surrounding out-door air, the houses act as draught-flues, and suck air out from the ground as if they were cupping-glasses set over it."

The Rights of Medical Experts.—The *Boston Medical and Surgical Journal* reports a decision of interest to physicians, which has been recently given in the Superior Court at Boston. A lady received a severe injury resulting from a defect of a street in Lynn, Mass., and after a long contest, involving four trials, succeeded in recovering heavy damages. At three of these trials her attending surgeon was called as a witness, and was examined not only as to knowledge of the facts in the case, but also as an expert on the anatomy of the part injured, the probable results of the injury, and the prospects of the patient's recovery, and was also consulted on these matters by the plaintiff's counsel before the trial, a promissory note being given for his professional opinion. Payment of this note was afterwards refused, on the ground that there was no legal consideration for their promise to pay, holding that a medical man is bound to testify to anything he may happen to know relevant to a case in court, whether it is a matter of fact in the particular case, or of general professional knowledge or opinion. The court, however, disallowed this defence, and ruled that a physician is not bound to give his professional opinion for nothing in court any more than elsewhere, and the jury found a verdict for the full extent of the claim. Although this decision was not given in the highest State court, it affords a precedent which will probably be followed, although in other States there is a conflict of authority on this point.

Surgical Triumphs.—Prof. Nussbaum has just published a very interesting address delivered on the anniversary of the hundredth birthday of Philipp Franz von Walther, who was born in 1782 and died in 1849. After an interesting account of his life and work, Nussbaum makes a rapid survey of progress since Walther's day. Anæsthetics, antiseptics, and bloodless operations, are all advanced as surgical triumphs. Of ovariotomy he says, "About 40,000 years of life have already been gained for women by successful ovariotomies;" and he believes that lives will be saved and much suffering prevented by Hegar's operation of removing the ovaries to anticipate the climacteric age in women, the subjects of bleeding uterine fibroids. The cure of reflex epilepsy by nerve-stretching he regards as a great advance in therapeutics. Excision of a kidney, or of the spleen, of parts of a cancerous bladder or prostate, of the rectum, and of the pylorus, he also regards with confident hope of improving results; and he believes it "not quite impossible that diseased portions of lung may be successfully excised." Our German colleagues are certainly not behind us in courage and adventure. —*British Med. Journ.*, Jan. 14, 1882.

A Teratological Curiosity.—According to the *Presse Médicale Belge*, two united children have been recently exhibited in Vienna which surpass in interest the celebrated Siamese twins. They were born in 1877, at Lacona, in the province of Turin. They have each a well-formed head, and perfect arms, and a separate thorax with perfect internal viscera. At the sixth rib, however, they unite, and there is but one abdomen, one anus, one right, and one left leg. There is a penis and corresponding scrotum, but behind the latter there is a rudimentary male organ, by which a few drops of urine escape. From behind, two vertebral columns are seen, two sacrums, and three buttocks, the central one evidently being due to the fusion of two, and in it is a rudimentary anus. The true anus serves for both children. Each individual has power over the corresponding leg and not over the other; thus the right leg obeys the will of the right twin named Baptiste, the left that of the other twin named Jacob. Walking is therefore impossible, although the legs are strong. Each child is said to possess a distinct moral personality. Sometimes one is laughing when the other is crying; one may sleep while the other is awake. Usually the head and face of each is inclined laterally, but if one is held perpendicularly the other becomes almost horizontal. The condition of sensation in the legs is not stated in the account.—*Lancet*, Jan. 21, 1882.

Hygienic Value of the Electric Light.—The French scientific journal *La Nature* summarizes a communication from Dr. Javal, who believes that the electric light is absolutely without danger to the sight, in consequence of the amount of division which can now be obtained in it. *L'Union Médicale* also reminds its readers that similar researches of great interest from a scholastic point of view were published in that journal in May and July, 1881, including the researches of Dr. Cohn, of Breslau, who found that the electric light increases sixfold, as compared with daylight, the perception of yellow, and doubles the perception of green and blue. The observations of Dr. Blasius and Dr. Hoppe, in a discussion which took place at a meeting of the Brunswick Society of Natural Sciences, are also noteworthy. These scientists have shown that illumination by the electric light deserved preference over all other methods in use, for the following reasons: 1. It does not pollute the air with deleterious gases or other unhealthy products; 2. It induces a greater visual unity than with daylight or gaslight. The conclusion adopted by the meeting was that "the hygienic qualities of the electric light have not hitherto been appraised at their real value."—*British Med. Journ.*, Jan. 28, 1882.

Removal of the Uterus.—Dr. Atthill, Master of the Rotunda Hospital, removed the greater portion of the uterus last week, by a modified Porro's operation. The patient had suffered intensely for a long time previously. Malignant disease of the fundus of the uterus was diagnosed. The nature of the proposed operation and its risks were explained to the patient, who readily acceded to its being performed as a possible means of relieving her from her sufferings. She unfortunately succumbed thirty hours after the operation. Microscopical examination of the diseased portion of the uterus showed it to be an epithelioma. The cervix had not been encroached upon by the new growth, but a small portion of the latter had been left in the stump. There was little or no hæmorrhage. Death was probably due to collapse, but there was *post-mortem* evidence of acute septic (?) peritonitis. The specimen was exhibited at the last meeting of the Pathological Society of Dublin.—*British Med. Journ.*, Jan. 28, 1882.

Collège de France.—The Minister of Public Instruction has just determined upon the erection in the neighborhood of the Collège de France of a laboratory of biological physics. By the same decree Prof. Brown-Séquard and M. d'Arsonval, his assistant, are made directors of the laboratory.—*Gaz. Méd. de Paris*, Jan. 28, 1882.

REGISTRATION METHODS IN BRUSSELS.—In the city of Brussels, whenever a birth is registered, the Registrar hands to the parent, gratuitously, a little pamphlet of five pages, containing short and plain directions for the management of children. In Paris, where the mortality among infants is enormous, it is proposed to introduce a similar practice.

ABOUT THE BLIND.—According to the census returns, there are 3907 blind persons in the State of Pennsylvania.

The "Pennsylvania Institution for the Instruction of the Blind" will receive applicants between the ages of ten and twenty-five.

The "Pennsylvania Working Home for Blind Men" will receive those between the ages of twenty-five and fifty, to learn trades and receive employment therein.

And the "Pennsylvania Industrial Home for Blind Women" will instruct and employ blind females of twenty-one years and upwards.

These institutions are located in Philadelphia; the last two are supported mainly by legacies and benevolent contributions.

A WARNING TO DOCTORS.—The Chinese authorities of Shanghai recently issued a quaint decree respecting the neglect of physicians to attend at once on their patients, and the high fees which they charge. They give notice that it is the duty of all physicians to use their knowledge for the benefit of the people; when people are sick they must be ready to attend upon them whenever they are sent for, without regarding the hour of the night or day, or the state of the weather. When people are ill they long for the presence of the doctor as the grain of seed longs for the rains. Instead of doing this, however, the physicians now think that they possess great skill, and not only charge high fees, but insist on being paid full hire for their chair coolies, and they do not care what becomes of the patient so that they get their fees. If these were only charged to the wealthy it would not so much matter; but the poor have to pay them also. An evil practice (the decree declares) also exists by which doctors will not visit their patients before one o'clock in the afternoon. Some will even smoke opium and drink tea until late in the evening. These are abuses, the magistrates say, which they will on no account permit. Doctors must attend their patients at all times. They must, if necessary, visit them several times daily; they must think more of them and less of their fees. Notice, therefore, is given to all officials and people, that a physician who does not attend when he is called, must only receive half his fees and half his chair hire. "If you physicians delay your visits, you show your wickedness, and sin against yourselves." The decree is a model one for a paternal government; argument, entreaty, objurgation, exposition, threats, are all mingled in due proportions.

In order to secure a proper degree of attention on the part of the native physicians, foreign merchants who employ them to attend their Chinese servants and other employés, are in the habit of paying them by the year, and docking off a proportionate amount for the time lost by their days of disability from sickness. This makes the physician anxious to cure the patient as soon as possible, so that his pay shall go on.

INCREASE OF THE PEABODY BUILDINGS.—On December 31, 1881, no fewer than 11,459 persons were in residence in the various groups of Peabody Buildings, showing an increase of 1565 upon the number at the end of 1880. This increase was mainly due to the completion and occupation, during the year, of two new groups of buildings: one in Whitechapel, and the other at Bedfordbury. The Whitechapel buildings were partly tenanted during June, and at the end of the year contained 1200 inhabitants. The smaller block of buildings, at Bedfordbury, contained 116 inhabitants at the end of September, but at the close of the year the residents had increased to 623. These new buildings at Whitechapel and Bedfordbury had 1823 inhabitants at the close of last year; it follows, therefore, that the residents of the older buildings were rather less numerous than at the end of 1880. It is scarcely possible to overrate the eventual beneficial influence of the Peabody fund upon the dwellings of the working classes in London, since the fund is increasing at compound interest. We await with interest the annual report of the trustees on the health of the residents in the Peabody Buildings during last year. Further efforts are, however, required to teach the working classes how to live healthily in healthy dwellings.—*British Med. Journ.*, Feb. 18, 1882.

PRIZES OF THE GENEVA RED CROSS SOCIETY.—The International Committee of the Red Cross, in Geneva, offers three prizes, each of the value of 2000 francs (£80), for the best essays in (1) improvisation of means of treating the wounded; (2) improvisation of means of transport; (3) improvisation of an ambulance or a field-hospital. The essays, which must not have been previously published, may be written in French, German, or English. The successful essays will become the property of the Society, which reserves the right of publishing them either in the original or in translation. Essays in competition may be sent up to April 1, 1883, to the President of the International Red Cross Committee, 8 Rue d'Athenée, Geneva.—*British Med. Journ.*, Feb. 18, 1882.

DIED, in this city, on the 7th of March, aged seventy-seven years, JOSEPH PANCOAST, M.D., Emeritus Professor of Anatomy in Jefferson Medical College. Dr. Pancoast was born in Burlington County, N. J., in 1805. He studied medicine at the University of Pennsylvania, and graduated in 1828. In 1838 he succeeded Dr. George McClellan as Professor of Surgery in Jefferson Medical College, and in 1861 was transferred to the Chair of Anatomy. In 1873 he resigned his professorship, and was elected Emeritus Professor of Anatomy. In our next issue we shall present a full sketch of the career of this eminent surgeon.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 28, TO MARCH 6, 1882.

COMEGYS, E. T., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Stanton, New Mexico, relieving Assistant Surgeon Newton.—*S. O. 40, Department of the Missouri, February 21, 1882.*

SPENCER, WM. G., *Captain and Assistant Surgeon.*—Relieved from duty in Department of the Columbia, to proceed to New York City, and, on arrival, report by letter to the Surgeon-General.—*S. O. 46, A. G. O., February 27, 1882.*

POWELL, J. L., *First Lieutenant and Assistant Surgeon.*—Fort Stockton, Texas. Granted leave of absence for one month.—*S. O. 19, Department of Texas, February 24, 1882.*

NEWTON, R. C., *First Lieutenant and Assistant Surgeon.*—When relieved by Assistant Surgeon Comegys, to proceed to Fort Cummings, New Mexico, and report to the Commanding Officer for duty.—*S. O. 40, C. S., Department of the Missouri.*

FRANTZ, JOHN H., *Major and Surgeon.*—Died at Baltimore, Md., on March 2, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XL. SATURDAY, MARCH 18, 1882. NO. 11.

ORIGINAL LECTURES.

ADDRESS TO THE GRADUATING CLASS OF BELLEVUE HOSPITAL MEDICAL COLLEGE.

Delivered March 15, 1882.

BY JOHN S. BILLINGS, M.D.,

SURGEON U. S. ARMY.

I VAGUELY remember that once upon a time—a long while ago it seems, for I look back at it across the gulf of a great war, in which the days were like weeks, and the months almost counted for years—I spent one evening on a platform in a large hall, in the character of a new graduate in medicine. A part of the ceremonies on that auspicious occasion consisted of a valedictory address to the graduates, delivered by the most eloquent member of the faculty—an address which was highly praised, but of which I have vainly tried to remember either the ideas or the phraseology. Fearing that this specially localized loss of memory might be a symptom of a new nervous disease which I should have to name and describe, I have consulted several of my medical friends as to their experience in this respect, and I am much pleased to be able to say that I have found very few who have not totally forgotten the words of congratulation and of counsel given to them when they received their diplomas.

Nor is the reason of this far to seek. The new doctor, in the pride and vigor of youth, just stepping out of leading-strings, and realizing that he is really his own man at last—standing at the threshold of that wonderful, glittering world which beckons him on so enticingly, and in which fame, and love, and wealth await his coming—this learned and skilful physician is held back yet another hour, and compelled to listen to advice from one whom he does not know, but who can surely have nothing to tell him beyond some well-worn platitudes about the dignity and honor of the profession which he has chosen, and that if he will be virtuous he will be happy, or words to that effect. Small wonder then that, after a moment's attention, his thoughts wander, and he drifts away on that beautiful river of revery upon whose banks are Spanish castles unmatched by those of the Rhine or the Danube, and which are in strange contrast to the practical, prosaic, warehouse sort of a view which his orator is trying to present. If, therefore, I observe five minutes hence that some of my special audience here, the new graduates, are gazing reflectively upon some point of infinite distance, or are evidently magnetized by some particular wave in the sea of this other audience before me, I shall know that it is all quite as it should be, and that my remarks are fulfilling their purpose.

Being unable, as I have just explained, to remember what was said to me by way of valedictory, and never having been present at a similar ceremony from that day to this, I thought it would be prudent to consult the literature of the subject and find out what is usually said upon such occasions. For this purpose I have examined about a hunded valedictory addresses, and have obtained from them a vast amount of instruction, and some little amusement. From them I gather that this is an epoch in your lives, that you are entering a remarkable age of the world's history (it is customary here to allude to steam and electricity), that you live in the most wonderful country under the sun, and that the eyes of the world are upon you. All are agreed upon these points, and also as to the importance and dignity of the science and art of medicine, and the necessity of continued study on your part to keep pace with its advances. But the addresses are not equally harmonious on all points. Some of them assert that the condition of medical education in this country is not altogether satisfactory, that there are some medical colleges (not, of course, the college of the graduates, but some other medical college) which might be spared, that there are too many doctors now, and more coming, and that some of these not only have not as clear ideas about the precession of the equinoxes, or the authorship of the book of Job, as a member of one of the learned professions should have, but that there are even graduates in medicine (of other schools, of course), to whom the addition of vulgar fractions is a stumbling-block, and correct spelling vexation of spirit. On the other hand I find some who assert, first, that the above statements are unfounded; second, that it is not necessary to know how to spell correctly in order to cure the chills or set a broken leg; and third, that the demand for higher medical education is essentially a pernicious aristocratic movement, calculated to oppress the poor, and prevent them from obtaining the sheepskins so desirable to cover their nakedness. As, however, I am sure that all of you are just now strongly in favor of higher medical education, without regard to what you may have thought about it a few weeks ago, or what you may think of it a few years hence, when you get a little steam-hatching machine of your own, I feel that I shall most contribute to the harmony which this occasion demands by—entirely agreeing with you.

Upon the whole, I came to the conclusion that on this occasion it is safest to talk platitudes; in fact, I must do this if I am to advise you as a body. The inexorable laws of statistics tell me that among you are those having the most diverse capacities, purposes, and destinations. Two or three of you will go on with your studies for the next ten or fifteen years, observing, experimenting, reading, and comparing, until some fine day you will know something that other people don't know, and will become writers and teachers, leaders in your profession, famous in your day and generation. One or two of you may become popular physicians, for whom being called in consultation is an everyday matter, and a large income a matter of course. Many of you will become plain, solid, common-sense practitioners, who will do a vast amount of good, be indispensable to the comfort and safety of the community, and be happy because satisfied, which is more than I can predict of the others. A few will abandon medicine because it does not pay, and turn to some occupation of better promise. And one or two will slip farther and faster down the broad, smooth path of dissipation on which their feet have already taken the first step, and will pass on to the inevitable end.

Fortunately for all of us, nobody knows who are to be the black sheep and who are to win the prizes. Each of you must live out that which is in your brains and blood, the result of generations gone before; but, you have also to live out that which you yourselves add to the inheritance.

Now you are going out into Vanity Fair duly armed and equipped, and provided with maps and guide-books of the latest and most approved editions. Probably you will never again be so fully conscious of, or so thor-

oughly satisfied with, your knowledge of the science and art of medicine as you are to-night. What would I not give now to know as much as I thought I knew the day I received my diploma. And yet the seven world problems of Du Bois-Reymond are still unsolved.

I congratulate you on your prospects. Shall I tell you what some of them are? Our American life will present to you as much variety, as vivid contrasts, as subtle mysteries, and as many giants, demons, and sirens to be overcome or outwitted as any that the legends of old depict. No doubt you will soon come across some of that curious sect, the *antis*, who are beginning to make their appearance amongst us; anti-vaccinationists, antivivisectionists, anti-anything, so that it gives them an excuse to keep their names before the public. And when you are asked how you account for the voluminous statistics and startling facts which some of these antis produce so rapidly and easily, you may hesitate a little, unless you have heard the celebrated conundrum which I am about to give you. A little boy said, "That girl is the daughter of my father and my mother, but she is not my sister. How do you account for that?" And the answer is (this is strictly confidential), that the little boy lied. Taking them all in all, these antis are a curious class of cranks, worthy of careful study on the part of some of our experts in mental diseases, during the brief intervals in which they have no medico-legal case on hand. Some of them are quite honest in their convictions, and all are very theological and emotional in their appeals, and to this they owe what success they have in achieving notoriety; and yet, while professing the most humane sentiments, they are unscrupulous even to cruelty in carrying out their fantastic ideas. They will not greet your coming on the stage of action with any particular enthusiasm, but you must not be discouraged on that account.

You will find, also, that the manufacturing pharmacist is abroad in the land, and that he, on the other hand, will be very glad to make your acquaintance. He will not only supply you with toothsome preparations, neatly put up in artistic packages, but he will tell you what they are good for, in what doses to use them, and, most important of all, which of them are in accordance with the code of ethics. He will ornament your office with innumerable samples, and pleasantly interrupt and variegate the perusal of your medical journals by means of blue, green, and yellow advertising sheets, unexpectedly and neatly inserted. Under his friendly guidance the path of medicine becomes a flowery one, for all that you have to do is to decide upon the name of the disease of your patient, and then look over the advertisements and samples to see what will cure it.

Moreover, there are some canvassers, and publishers and editors, who are prepared to be your best friends if you will only permit it. They want you in the first place to subscribe, and then to write; to produce from the stores of your knowledge, items, and essays, and papers, to help them to raise the standard of American medical literature, until it shall be high above that of the effete despotisms of Europe. Nor are these the only persons who await your coming. You are wanted in Medical Societies, the advocates of higher medical education rely on your support, Boards of Health and Registrars are looking to you to make their statistics perfect and complete, and Army and Navy Medical Examining Boards are preparing fresh lists of questions for your benefit. But perhaps you flatter yourselves that you have now passed your final examination. Never was a greater mistake. Your most severe and continued ordeal is just about to begin. And it may be that the result will give rise in some of your minds to serious doubts as to the value of the Darwinian theory about the survival of the fittest. But at all events I can assure you that you need have no fear as to there not being room for you, or that the world has not work enough for you to do. You know the old saying, "There is always plenty of room on top." But even in the lower stories there is plenty of standing room. There are to-day between one and two millions of sick persons in the United States, and the deaths for this year will certainly be a million. You see, therefore, that the sanitarians, whom some of you may, unwisely, look upon as enemies, since they are trying to do away with some of the causes which necessitate your services, have, at all events, not yet seriously injured the business of the profession. And for your further encouragement I will predict that it will be a long time before they succeed in doing this, for whatever variations the changing seasons bring to our other harvests, the fool crop continues with almost unvarying regularity.

While I am on this subject, however, let me advise you from the business point of view, as well as on account of your interests as citizens and humanitarians, to look into this matter of preventive medicine a little more closely than you have yet probably had time to do. It is going to be a very important matter in your day and generation, and you will be examined and cross-questioned on it to an extent which you little suspect. Some of you will no doubt be called to act as members of Boards of Health, and all of you are sure to be appealed to on questions of ventilation, house drainage, school hygiene, pure water, adulterated food and drugs, and the means of shunning or putting away the pestilences, which will consume, not only the children of other people, but your own also, if you cannot answer the sphinx's riddle.

You will find that public health legislation is a matter to which you cannot remain indifferent, for you will become part of the machinery whether you wish to or not, and if you are wise you will study the subject so that you can aid in shaping this legislation to what it should be, for in this respect knowledge is power. If you leave the matter to sentimental enthusiasts and professional office-seekers, you will find that it will turn out like the Irishman's ale—it will thicken as it clears. One of the matters just alluded to touches your professional work very nearly, and that is the adulteration of drugs. If you practice in a large city, this is not of so much importance, since you can always readily find first-class pharmacists, upon whose preparations you can rely, but away from the great centres, the case is different. Unless you can depend upon getting what you call for in your prescription, what success can you hope for? and yet unless you know what apothecary is to fill that prescription, you cannot rely upon it. And it is always wise not to conclude that your treatment has failed until you have made sure that what you ordered has really been given.

And in this immediate connection, permit me to remind you why the hyrax has no tail. It is written in the mystic volume of St. Nicholas that when the world was about being completed, notice was issued to all the beasts that, if they would go to the Court of the King on a certain day, they would be handsomely finished off with tails. All were pleased with the prospect, but the hyrax was especially delighted. Now when the appointed day came, it was cold and rainy, and the hyrax did not like to go out in bad weather. So he stood in his door and asked the lion and the wolf and several others to bring him his tail, and they all promised to attend to it. But they all forgot it; and when the hyrax went himself the next day to see about it, he found that the supply of tails was exhausted. That is why the hyrax has no tail, and if you rely on what other

people tell you that they have done, or are going to do, for you, the result will probably be about the same.

And just here permit me to give you an entirely new bit of advice; at least, I did not find it in any of the valedictories I read. You will, of course, never ask a man who is not acquainted with you personally to give you recommendations or testimonials; but see to it that you yourselves never sign a recommendation for a man whom you do not know. Do not be persuaded or bullied into doing this by people whom you know, for people whom they know, but you do not. If you wish your name and opinion to have any value in the eyes of other people, respect them yourself.

Do not be in a hurry to write or teach. The American press has been said to be chronically premature, and the same may be said of a good many graduates—not, of course, of this school, but of some other schools; and not only in this country, but in other countries. There are a great number of men, in all professions, and in all parts of the world, of whom it may be truly said, that if they knew more, they would say less. Try to know something of all branches of science, for they all throw light upon your work; and at the same time try in some one branch in your own special field of study to know more than anybody else, and to be sure that you really do know it. This is not so difficult as it may seem. You will not have to go far in any direction before you will come upon that which is doubtful or unknown—questions which as yet have no answers. And if, during your pupilage, you have learned to think, and are not, as Holmes phrases it, merely "phonographs on legs," the rest is a mere matter of detail, and this advice is not difficult to follow. Hesiod said that in his day there were three kinds of men—those who understand things of themselves, those who understand things when they are explained to them, and those who neither understand things of themselves nor when they are explained to them. That was the classification in Greece over two thousand years ago, but it is a convenient one for use even now; and when a man has settled for himself to which class he belongs, his education has taken a long stride.

Each of you has his aspirations—a little vague, no doubt, but none the less real. Keep them as long as possible, and, above all things, do not assume or affect a cynicism which belongs neither to your age nor your experience. Second-hand misanthropy is like a second-hand Chatham Street coat: it never fits. No doubt you all desire to make money; not for the money's sake, but for what you can do with it. It is not a desire to be ashamed of, and the business side of your profession demands your careful attention. But mark this: The best works in this world are not done for money, or from selfish motives of any kind. And if you are to achieve true success—the success which brings happiness, and is the only kind worth seeking—you must do a vast amount of work, not for money, but in part because you like it, and in part because it will do good and help others. Do not wait for the opportunity to do some great thing. Take hold of the work that lies next your hand; work which you can do, and which ought to be done—it will be very strange if there is not always something of that sort waiting for you; and do not dawdle, and defer, and lose the good, in a vain waiting and longing for the best.

Be healthy, brave-hearted, and joyous. Physical health is unfortunately not contagious, but mental and moral health is. Avoid second-hand philosophy, sickly complainings about the evils and miseries of life, and small beer of all kinds. No doubt you will find many of your golden dreams fading into gray mists; but, on the other hand, you will be continually stumbling against solid realities, which are quite as good as any dreams if you only recognize the opportunity. Labor and trouble you must meet; but of the first you can for the most part make a pleasure, and the second should not be pampered and made a luxury of. Never pity yourselves. Do not waste your time in vain speculations as to the why. Remember that bitter little poem of Heine's:

"By the sea, by the dreary, darkening sea, stands a youthful man,
His head all questioning, his heart all doubting,
And with gloomiest accent he questions the billows.
Oh, solve me life's riddle, I pray ye, the torturing ancient enigma
O'er which full many a brain hath long puzzled. . . . .
Tell me, what signifies man? Whence came he hither?
Where goes he hence? . . . .

"The billows are murmuring their murmur unceasing,
Wild blows the wind, the dark clouds are fleeting,
The stars are still gleaming so calmly and cold.
And a fool is awaiting an answer."

In the majority of valedictory addresses which I have examined, there was more or less special advice about medical ethics, and a word or two on this subject is therefore not out of place. The code—or perhaps I should now rather say the codes—of medical ethics are great mysteries to the public at large. By many it is supposed to be a sort of trades-union set of rules designed to protect the business interests of physicians, without any particular regard to the rest of the world. I need hardly say to you that this is not true. It may be summed up in this, that a physician should be a gentleman, and should treat other physicians and his patients as he would wish to be treated under like circumstances. And your duty in this matter is to attend to your own ethics and not those of other people. Medicine is not a rigid system of rules and formulæ as it was in ancient Egypt; a fixed creed to which you are to subscribe, and from which you must not vary. It is a living, growing thing, making use of every resource which the progress of science brings; it is truly eclectic and catholic, testing all things, and holding fast to that which is good. It is not a system which forbids the use of any particular remedy, or limits its followers within the narrow bounds of any sect or ism. There are such systems, and there are a few men who advertise themselves as followers of such systems, and who really do follow them. There are also many men who so advertise, but who really do not follow them. Some of these last are well-educated physicians, "but they are—that is to say, from the point of view of a gentleman, they must be considered as—in short, the more you know of their methods the more fervidly you will assent to what I have not said about them."

One of the latest authoritative expressions of opinion on this subject is the following resolution recently adopted by the Royal College of Physicians in London:

"While the College has no desire to fetter the opinion of its members in reference to any theories they may see fit to adopt in connection with the practice of medicine, it nevertheless considers it desirable to express its opinion that the assumption or acceptance by members of the profession of designations implying the adoption of special modes of treatment is opposed to those principles of the freedom and dignity of the profession which should govern the relations of its members to each other and to the public. The College, therefore, expects that all its fellows, members, and licentiates will uphold these principles by discountenancing those who trade upon such designations." This last sentence touches the root of the difficulty. *Those who trade upon such designations.* Let us take a concrete example. You treat a case of pemphigus with arsenic. You may theorize as you like about the essential nature of pemphigus; you may select arsenic because you think it would produce the disease, or because you think it produces something contrary to the disease, or for no reason whatever beyond the empirical fact that you

have seen a case of pemphigus recover under the use of arsenic. Also, you may give this arsenic alone or combined with other substances, and in any doses that you please, from the decillionth of a grain to a grain, and you may explain the results as you like. But as an educated physician, and a gentleman, you may not advertise yourself as an arsenio-pemphigist, and denounce every one who does not adopt your theory and practice, and as there is a good deal of common-sense truth in the old adage, that a man may be known by the company he keeps, you will not have more to do than you can help with the men who do so advertise themselves; and still less will you have to do with those who advertise themselves as antiarsenio-pemphigists, and then treat their cases with arsenic after all, and claim the results as due to dynamized brickdust.

And please observe that this is all that you have to do. You are not to enter into controversies with them or about them, you are not to repine over their success or exult over their failures. They have another code of ethics from your own; that is all that need be said about it. Thus far I have been speaking of fairly educated sectarian physicians. As to the ordinary, uneducated, and bill-distributing quack, with his sure cure for cancer, or his pure vegetable specific for coughs, rheumatism, and dyspepsia, you may be sure that in the long run he will make rather more business for you than he takes away. Do not fall into the error of supposing that legislation can prevent the existence of this class of men, or that you need the protection of the law against them. The public interest demands such protection, if for no other reason than to secure a proper registration of the causes of death of all citizens, and it is not only your right, but your duty, to call the attention of legislators to these interests, but never seek protection on your own account.

Be honest to yourselves as well as to other people, and do not be afraid of admitting that you do not know, or feel bound to attempt an explanation of all that you see or do. He who would know anything thoroughly must be content to be ignorant of many things. Try to define to yourselves, as clearly as possible, your own ignorance; it is the first step towards remedying it, and be sure that the modest student, whether he be undergraduate or learned professor, will everywhere meet with helping hands in the great brotherhood of science.

There are many men who are honest in purpose, and yet who are constantly, although not consciously, untruthful; they see that which they think they ought to see, and not that which is.

I am reminded that this is a valedictory address, and that in it I must bid you farewell. This I do in behalf of your teachers, whose unavailing regrets that they are not to have another opportunity of meeting you in the examination-room, you can imagine much better than I can describe. What they could do for you they have done. And now, as Emerson says, "We have accompanied you with sympathy, and manifold old sayings of the wise, to the gate of the arena, but 'tis certain that not by strength of ours, or of the old sayings, but only on strength of your own, unknown to us or to any, that you must stand or fall." You may be sure of our best wishes for your success and happiness.

"Who misses or who wins the prize, go lose or conquer as you can;
But if you fall or if you rise, be each, pray God, a gentleman."

But while I bid you farewell as students, I also bid you welcome to the ranks of the profession. And I can assure you, that upon the whole, you are coming into very good company. If in anything I have said this evening I have seemed to speak lightly of the medical profession or its adjuncts, I hope it will not be construed as more than the ordinary banter in which we boys sometimes indulge when we get off in a corner by ourselves.

I have much faith in the advice of that anonymous writer who said—

"Oh, never wear a brow of care, or frown with rueful gravity,
For wit's the child of wisdom, and good humor is the twin.
No need to play the Pharisee, or groan at man's depravity;
Let one man be a good man, and let all be fair within.
Speak sober truth with smiling lips; the bitter wrap in sweetness,
Sound sense in seeming nonsense, as the grain is hid in chaff.
And fear not that the lesson e'er may seem to lack completeness,
A man may say a wise thing, though he say it with a laugh."

It is true that you are entering, nay, in your medical studies you have already entered, a world of labor, and pain, and sorrow. You will see how the destruction of the poor is their poverty, and how the sins of the fathers are visited upon the children; how neither culture, nor wealth, nor power, can forever put off the evil day; and how there is, at last, one event to all the sons of men.

You must be prepared to deal with anxiety, fear, grief, and despair, as well as fever and physical pain; you are to be not only physician, but friend, confessor, guide, and judge, and you cannot avoid these responsibilities if you would, nor should you if you could.

Nevertheless, I can assure that you are also entering a beautiful world, where the very shadows prove that plenty of sunshine exists, a world of brave men and good women, whose best and noblest characteristics are brought out most clearly and vividly in such scenes as those in which you will be called to act. But remember, that as a rule, you will find only what you seek and believe in. Remember, also, that this knowledge which you have acquired, and are yet to acquire, is entrusted to you as a power, a power none the less real, and involving no less responsibility because it is accompanied by no special outward insignia of authority or rank.

By the help of this knowledge you are to get wisdom—that wisdom which always lingers, and sometimes comes too late; that wisdom of which it is written that for all the children of men "length of days are in her right hand, as in her left hand riches and honor."

CLINICAL REMARKS

ON MUSCULO-SPIRAL PARALYSIS.

Delivered at the Orthopedic Hospital and Infirmary for Nervous Diseases, Philadelphia.

BY S. WEIR MITCHELL, M.D.,
PHYSICIAN TO THE INFIRMARY.

(Reported by GUY HINSDALE, M.D.)

MORRIS F., æt. thirty, a driver, applied at this hospital November 25, 1881, with the following history: He says that he was well until fifteen weeks ago, when he was thrown off a cart against a railing, striking his collar-bone and breaking it by direct contact. He also states that his shoulder-blade was out of place. The luxation having been reduced and the fracture set, in due time union took place and he returned to his work.

During this treatment his fingers upon the affected side gradually became a little numb, and for a while there was difficulty in moving them. After working for a fortnight, however, he suddenly lost the use of his hand, and was compelled to stop. On being questioned further, the patient states that on November 19, after drinking largely, it being Sunday afternoon, he went to sleep with his arm hanging over the edge of a settee, and that on awakening he found his hand benumbed. The following morning this numbness had increased, but now the arm is mending slightly.

Upon listening to the patient's history we find in the remote distance a possible cause, but which, in all probability, has nothing to do with his present trouble. It is, in fact, a very rare thing to see a fracture of the

clavicle produce great injury to the brachial plexus; but it is strange that such a result does not happen oftener, considering the relations of the various important structures lying in the sub-clavicular region. An account of cases of nerve-injury after fracture of the clavicle and luxations of the shoulder-joint, may be found in my book entitled *Injuries of the Nerves*.

Our patient says that at first he was unable to shut his hand tightly; now his grip is good. He cannot, however, extend the fingers, but is able to flex the second and third phalanges, though not the first.

The ulnar and median nerves perform their functions correctly; the musculo-spiral is the nerve injured. This is evident from what we learn of the man's position during the sleep which resulted in paralysis. His arm being extended, and resting on the edge of the settee at the point where the musculo-spiral crosses under the humerus, injury to the nerve at this point was quite possible. An examination of the muscles brings us to the same conclusion. When, having flexed his arm, I ask this man to resist me as I forcibly extend it, I find that, although he is a right-handed man, his right arm is the weaker. The action of the biceps is as good on one side as on the other, but on the right side there is absence of aid on the part of the supinator longus, which does not contract so forcibly on the affected side as upon the left. The muscles at the back part of the arm, the extensors, are in perfect working order.

The nerve is therefore injured between the points at which arise a branch to the triceps, which is unhurt, and those branches of the musculo-spiral which are given off below. There is no numbness in the forearm; the ulnar and median distributions are not affected. The thumb, however, is numb, and there is some want of feeling on the dorsum of the hand; in other words, the radial—the continuation of the musculo-spiral—has been partially paralyzed. The muscles of the forearm and hand react well under the electric current, when it is applied either to the nerve or to the muscles.

A case of this kind shows the necessity of going carefully into the anatomy of the part. The history would lead one to suppose that the phenomena were due either to the luxation or to the fracture of the clavicle, especially as there is a good deal of callus at the external end of the clavicle. If, however, the disturbances were due to this latter cause, they would have come on gradually; but, on the other hand, they arose abruptly, after sleep.

I have seen a great many of these cases. A man in a drunken sleep lies with his arm pendant over the edge of a chair or sofa, and wakes up paralyzed as to the musculo-spiral distribution. In one case, reported in my book, a drunken man fell in the sleep of intoxication so that one arm rested on the edge of a stone door-step, and the other on the sharp top of one of our old-fashioned foot-scrapers. He awakened with a double radial palsy.

It is a little odd that while, if we may trust the published cases, nerves violently stretched get well readily, nerves compressed like this man's do certainly prove very difficult to restore to absolute health.

The treatment consists in faradic excitation chiefly; and, as the man is already improving, we may with reason hope for a permanent and rapid recovery.

ORIGINAL ARTICLES.

AN IMPROVED PLAN OF USING CHRYSOPHANIC ACID EXTERNALLY.

By GEORGE HENRY FOX, M.D.,
of New York.

It must be admitted by all that no recent addition to dermatological therapeutics can compare in value with chrysophanic acid. External applications of this remedy remove with surprising rapidity the most inveterate eruption of psoriasis, and prove of value in other cutaneous affections. But its action is difficult to control. As all know who have had experience in its use, it is very liable to produce a severe and unexpected dermatitis, and almost certain to ruin the underclothing and bed-linen of the patient. These objectionable features I have endeavored to obviate by adopting the following method of applying the remedy: A soft paste is made by rubbing the chrysophanic acid with a sufficient quantity of water and smeared upon the psoriatic patches, the scales of which have been previously removed, by one or more hot baths, with soap friction. As soon as the paste has dried, which it does in one or two minutes, a layer of collodion should be allowed to flow over each patch and to harden into a protective coating. This will remain in place for several days or longer, according to the location of the patches, and when it falls or is washed off, the application of the powder and the collodion should be repeated. By this procedure the chrysophanic acid in full strength is kept in contact with the affected skin, and prevented from exciting undue inflammation of surrounding parts or staining the clothes. A mixture of the powder and the collodion may be used, but it is less efficacious. A film of the collodion doubtless interferes with the action of the acid upon the skin. A somewhat similar plan which I have tried consists in the use of gutta-percha tissue to retain a strong chrysophanic ointment in contact with psoriatic patches. The edges of this tissue will adhere tightly to the skin if a small camel's-hair brush, dipped in chloroform, is passed rapidly beneath them.

BOVINE *vs.* HUMANIZED VIRUS

AS AFFECTING THE PREVALENCE AND DEATH-RATE OF VARIOLOID.

By CHARLES SMART, M.D.,
U. S. Army.

In connection with the present small-pox service in the city of Washington, D. C., I had occasion recently to inspect a "vaccine farm," from which, during the past month, a number of quills had been obtained for the use of the health office. After examining the details of the propagation of the disease from calf to calf, and the transfer of the matured virus to the quills, I watched the results of the implantation of the virus in forty consecutive cases—inmates of the Deaf and Dumb Asylum, at Kendall Green. Usually in testing virus I have endeavored to have the consecutive cases primary, so that no influence of previous vaccination might underestimate the value of the material. The operations were performed by Dr. Walsh. Of the forty cases, six only were primary implantations. These were successful, and ran the definite and well-known course of the vaccine disease. Of the thirty-four secondary cases, or revaccinations, all presented more or less indication on the arm of a previous operation, and one, in addition, was well pitted from an attack of small-pox, presumably modified by his antecedent

vaccination. In four of these the virus failed to produce its specific local results, while in thirty, among whom was included the individual who had previously suffered from small-pox, the results were successful, that is, the local inflammation, maturation, and crusting ran day by day parallel with the same manifestations in the primary cases, so that from the recent appearances on the arm it could not be said whether an individual case was a primary or a second vaccination. Experiences of this character have no doubt been noted by most physicians who have been making use of bovine virus, but I do not think that the inference which may be drawn therefrom has been placed prominently before the profession.

Of late years the belief has been gaining ground that humanized vaccine has become deteriorated by its transmission from patient to patient through so many years, and that the protective influence has thereby been lessened. Statistics show that the mortality from varioloid is greater now than during the years when vaccination was first practised. But that this is owing to the cause alleged, seems more than doubtful. Many practitioners of large experience believe it to be due to imperfect vaccination from improper crusts and a failure to repeat the operation until a satisfactory result is obtained, or, in other words, that the implantation of a material which may or may not have contained the specific particles, has been too often recorded as successful if any local action followed its introduction, although that action may not have been characteristically specific. No matter which may be the correct view to take of the increased mortality, the first theory has to be credited with the introduction of bovine virus into this country. The certainty of its action, with the facility of obtaining it when required, has led to its general adoption, irrespective of a probable improvement in the immunity statistics, which may be shown in the future.

Humanized virus, when propagated by the arm-to-arm method, is probably as certain in its specific local action as fresh bovine virus; but it is impossible to accomplish a large undertaking in this way. So, also, recent humanized virus on quills, points, glass slips, or in sealed tubes, yields but few failures in primary cases; but these cannot be so generally obtained as the points from the bovine culture. Practically, the bovine quill or point has to be compared with the humanized crust, preserved in wax, and rubbed up when required with water or glycerine, with which general vaccinations not long ago had to be effected. A percentage of failures would occur in primary cases vaccinated with this material, each requiring repetitions of the operation to effect a successful vaccination; while in revaccinations, with a small percentage of characteristic successes, there would be an exceedingly large proportion of anomalous "sore arms," and a certain number of clearly defined failures. When due care was taken to use only crusts which had responded satisfactorily in primary cases, to make two or three aggregations of insertions on each individual, and to infect each aggregation with material from a different source, the vaccinator considered himself warranted in assuming that immunity for a certain period had been conferred on the first or characteristic cases; that the failures were already protected against variola, and that the anomalous cases were vaccinia modified and irregular in its course by the influence of a previous vaccination. If these anomalous cases were really modified vaccinia, the susceptibility to the small-pox poison was exhausted by the operation, and they were entitled to be recorded as successful cases of revaccination. That they were thus viewed and recorded by the majority of vaccinators I feel confident from the large percentages of successful revaccinations appearing from time to time in published statistics — percentages which, in my own practice, I could only approach by including those cases where inflammatory action followed the operation, with crust-formation falling off at various times, say from the tenth to the twentieth day. But it is difficult to feel assured of success and protection in these anomalous cases resulting from humanized virus in a previously vaccinated individual in view of the distinctly specific character of the thirty cases recorded above as resulting from the introduction of the bovine virus. Even the case which had suffered from a previous attack of small-pox presented characters similar in every respect to those of the previously unvaccinated baby. This, however, might be set aside as owing to a peculiar and unusual susceptibility, like that unfortunate case which occurred in this service only the other day, where the carpenter employed on the repairs of the hospital, and selected for that employment because he had already suffered from the disease, became infected a second time, and died. But the absence of any irregular action in these thirty-four revaccinations throws grave doubts upon results which, I believe, have hitherto been regarded as satisfactory.

If modified vaccinia has no existence except as a product of the implantation of the humanized crust, the local action consequent on such an implantation must be referred to the introduction of non-specific organic matters—blood and inflammatory products more or less affected by aeration. And if such cases have gone on the record as successful revaccinations, the spread of modified small-pox, and its increased mortality, can easily be accounted for. Fortunately, while indicating the probable origin of the increased prevalence and severity of varioloid, the bovine virus may be expected to remedy the evils, although time must necessarily elapse before statistics can be brought forward to specify its influence.

IDIOPATHIC GLOSSITIS, TREATED BY ATOMIZATION—SPEEDY RECOVERY.

BY E. STUVER, B.Sc., M.D.,
OF RAWLINS, WYOMING TERRITORY.

I WAS called to see J. M., æt. twenty-one years, laborer, at 5 P. M., January 4, 1882, and ascertained that about two hours previously he had been taken ill, quite suddenly, with a severe pain in the region of the tongue and fauces, headache, and general malaise.

For a day or two preceding this attack, he had

noticed an impairment of appetite, slight headache, some soreness of the throat and muscular system, but did not desist from his usual employment.
